Treatment When joints are less seriously involved they are treated symptomatically, when purulent lesions are suspected or obvious, aspiration and drainage are desirable both for diagnosis and treatment Frames and braces may be necessary for spinal lesions (Snyder¹²¹) For the primary condition many consider the various medicines used (including neoarsphenamine) as of no value^{110, 125} A patient of Ching's¹²⁶ apparently responded to neoarsphenamine Satisfactory response to a triple typhoid vaccine febrile reaction in one case was reported by Beaumont and Page¹²⁷ Transfusions may be helpful¹²³ Vaccines of *Brucella* organisms are of debatable value some are disappointed with them, others regard them highly^{110, 111, 118, 125, 128, 129} Convalescent immune serum was used in one case with apparent success by Kretzler¹³⁰ and Kennan¹³¹ after vaccine had failed Further experiences with their new antiserum were reported by Wherry, O'Neil and Foshay¹³² 20 patients "responded favorably", two were doubtfully improved, four unimproved Failures were believed due to inadequate potency of earlier serums and to insufficient doses Foshay's *Brucella* antiserum was recommended by Ashworth and Pickney¹¹⁰

Of interest also are historical notes^{109, 111, 118, 133}, studies on the bacteriology¹¹⁵ and on the immunology of the disease^{134, 135}, its experimental production,¹³⁶ and its spontaneous occurrence in dogs¹³⁷

PYO-ARTHROSES PURULENT (SEPTIC) ARTHRITIS

As noted, gonococci or pneumococci may produce purulent arthritis The commonest form of pyo-arthritis in adults is from gonorrhea Pyo-arthritis is commoner in children, when it is generally caused by *Staphylococcus aureus* or hemolytic streptococci, usually secondary to juxta-articular epiphysitis or osteomyelitis Additional etiologic factors in Veal's¹³⁸ cases were abscesses, boils, infected burns, staphylococcal pneumonia, streptococcal sore throat, acute tonsillitis, acute torticollis, and postoperative infection of a popliteal aneurysm, in Inge and Liebolt's cases¹³⁰ otitis media, pyelitis and purulent cervical adenitis, in Overton and Meyerding's cases¹⁴⁰⁻¹⁴³ a knife stab and a nail wound The source of infection is often undetermined Monarthritides is generally present, rarely polyarthritides A hip or knee is generally affected, less commonly an ankle, elbow, or shoulder

The usual symptoms are fever, chills, redness, swelling, much tenderness, muscle spasm and articular distention from fluid. It is agreed^{138, 139, 144} that although roentgenograms show alterations in joints after a number of days, they are not helpful in early diagnosis so important for treatment if articular function is to be saved. For early diagnosis aspiration of the joints is most valuable and, if the first tap is "negative," should be repeated in suspected cases. One should try to be certain, however, that arthritis and not just periarthritis is present^{141, 143}. Insertion of a needle through a purulent periarthritis (as from a stab wound) may infect an otherwise unaffected joint. Cultures of aspirated pus may be negative, possibly owing to the bactericidal properties of synovial fluid¹⁴⁵. Cultures were negative in 55 per cent of Veal's¹³⁸ 68 cases, and in 39 per cent of the 36 cases of Inge and Liebolt¹³⁹. Cultures revealed staphylococci (generally aureus) in 25 per cent of Veal's cases, in 36 per cent of Inge and Liebolt's cases, in 60 per cent of Slowick's¹⁴⁴ 60 cases, and in 100 per cent of Martland's 8 cases¹⁴⁶. Streptococci (generally hemolytic) were recovered in 15 per cent of Veal's cases, 32 per cent of Inge and Liebolt's cases and in 39 per cent of Slowick's cases. Other bacteria occasionally recovered were *Bacillus pyocyaneus*, pneumococci, and mixed staphylococci and streptococci.

Three rarer forms of purulent arthritis were reported. A case due to *Micrococcus tetragenus* was reported by Reiman,¹⁴⁷ who found eight such cases with arthritis and two with arthralgia in the literature. Hematogenous osteomyelitis and pyo-arthritis due to *Salmonella supestifer* (hog cholera bacillus) were present in the case reported by Weaver and Sherwood¹⁴⁸, six other cases of such a pyo-arthritis have been reported. Thirty cases of pyo-arthritis due to *Haemophilus influenzae* (*Bacillus influenzae* of Pfeiffer) have been recorded and Peterson reported another¹⁴⁹.

Treatment Treatment concerns the patient, the primary focus of infection and the joint. Surgeons of the seventeenth and eighteenth centuries were content to try to save the life of a patient with pyo-arthritis. In the nineteenth century they tried to save life and limb, ankylosis being a small matter. In the twentieth century the aim is to save life, limb and articular function¹³⁹. All agree that early repeated aspirations or drainage are imperative, but opinions differ on the methods of drainage (simple aspiration, aspiration and irrigation, incision and drainage, arthrotomy). The procedure must be suited to the case under treatment. Amputation is even occasionally necessary^{138, 150}. Indications for these different procedures have been restated by several^{19, 138, 139, 146, 150-153}. Splints and casts may be necessary^{144, 146}. Postoperative physiotherapy and early joint motion are favored by some,^{139, 145} used cautiously by others¹³⁸. Of three plans in current favor (1) drainage and active mobilization (Williams, 1919), (2) drainage, immobilization and traction (Harris, 1925) or (3) joint washing, closure of the joint and temporary immobilization (Cotton, 1916, 1920), Jones¹⁴⁵ favored the third, that is arthrotomy, washing the joint with physiologic saline solution or with 1:15,000 bi-

chloride solution in saline, and then suturing. Matland¹¹⁶ favored the use of proflavine intra-articularly, and euflavine and antistaphylococcal serum intravenously. Staphylococcal bacteriophage for purulent staphylococcal arthritis has been advocated (Rice, 1930, Wiant and Mirallie, 1931, Flury, 1931). Its value was questioned by Gregorie (1931). Inge and Foumey¹¹⁷ found it of no value to one patient, and also not helpful in the treatment of experimental staphylococcal arthritis in dogs. Bacteriophage is probably inactivated by body fluids.

Staphylococci are not killed even by the application of 100 hours of heat at 106.7° F (41.5° C). Staphylococcal infections would thus seem to be impervious to fever therapy. However, a diabetic patient with an apparently hopeless case of staphylococcal septicemia was reported as having recovered after fever therapy prescribed in desperation (Hartman¹¹⁸).

Course and Prognosis, Results of Treatment. The course of pyoarthrosis is limited and not progressive as in "nonspecific infectious" (atrophic) arthritis. Little loss of function may result if treatment is adequate, at other times great destruction and deformity ensue. Arthroplasty and other corrective procedures are later indicated^{20, 152, 153}.

Of Slowick's¹⁴⁴ patients, 22 per cent regained excellent joint function, 40 per cent good or fair function. The mortality was 20 per cent in his cases, 18 per cent in Veal's¹³⁸. As the cases of Inge and Liebolt again showed, results are often (54 per cent) good when the condition is not complicated by bone infection, poor otherwise¹³⁹.

TYPHOIDAL ARTHRITIS AND SPONDYLITIS

Typhoidal arthritis occurs in 1 to 10 per cent of cases of typhoid fever. Since typhoid fever is becoming rare in the United States, typhoidal arthritis is also becoming very rare, particularly "typhoid spine," one of the less common varieties of typhoid arthritis. No recent reports have been available for our Reviews. Up to 1932, only about 150 cases of typhoid spondylitis were reported (Wang and Miltner, 1932) and only one necropsy recorded (Rugh, 1915). Gambee¹⁵⁵ briefly reviewed the symptoms of the condition and gave 17 references thereon from 1889 (Gibney, who named "typhoid spine") to 1932. In light of newer knowledge of the physiology of the intervertebral disks, Gambee has attempted to explain the pathogenesis of the different varieties of "typhoid spine" and why lumbar vertebrae are particularly affected. Appended was a case report on operative drainage of a vertebral abscess which developed four years after the patient had apparently recovered from typhoid spine.

A boy (age unstated) had typhoid fever in 1929, complicated by empyema and a pararectal abscess. Severe lower thoracic and lumbar backache developed, with fever and muscle spasm, and lasted about three months. A diagnosis of typhoid spine was made (no mention is made of roentgenograms—Ed). Four years later, after swimming, low backache, muscle spasm and kyphosis developed. Roentgenograms revealed fusion of the third and fourth lumbar vertebrae and partial obliteration of the inter-

vertebral disk, interpreted as a long-standing affair more like typhoid spondylitis than tuberculosis. The Widal test was negative, no typhoid bacilli were found in stools. Leukocytosis (15,750 cells) was present. At operation, an abscess of the affected vertebral bodies and intervertebral disk was drained. On culture the pus revealed a few gram-positive cocci but no typhoid bacilli. The guinea-pig test for tuberculosis was negative. Pain and fever promptly subsided and convalescence was uneventful.

(It is regretted that no report on roentgenograms during the initial fever was given and that the recent roentgenograms were not reproduced. Considering the prolonged viability of typhoid bacilli in the human body (e.g., in the gall-bladder) a diagnosis of "typhoid spine" seems possible, but in the absence of bacteriologic proof the diagnosis is presumptive.—Ed.)

ARTHRITIS WITH CHRONIC ULCERATIVE COLITIS

Of 1,500 patients with chronic ulcerative colitis of the type believed due to the diplostreptococcus of Bergen, 60 had coincidental arthritis. Arthritis was the commonest "complication" except polyposis (in 130 cases) and stricture of large intestines (in 110 cases). Bergen¹⁰⁰ and Hensch¹⁰¹ thought that this association cannot be explained satisfactorily on the basis of coincident association of two independent diseases, but that a specific complication and a specific type of arthritis may be present in some of these cases. Analysis revealed four types of relationship: (1) that in which arthritis preceded the colitis by a fairly long time, the arthritis was considered unrelated to the colitis and was generally of the atrophic, rarely of the hypertrophic, type (as chronic ulcerative colitis is a disease of early life), (2) that in which both atrophic arthritis and ulcerative colitis came on more or less together but in which each disease thereafter seemed to progress quite independently, neither being particularly affected by variations in the other, (3) that in which an arthritis resembling atrophic arthritis affected a patient who already had severe ulcerative colitis, but in which exacerbations in joints appeared during remissions, not with exacerbations, of colitis, and (4) the more common type of association—that in which a subacute arthritis appeared with the onset, or more frequently with a subsequent exacerbation, of severe colitis after which the patterns of both diseases showed a striking conformity, remissions and exacerbations of both appearing simultaneously, the joints often being relieved by measures directed to the bowels.

The first two and possibly also the third type of case were believed to represent an unrelated coincident association of ulcerative colitis and atrophic arthritis. The fourth and more common type of case was tentatively thought to represent a specific relationship. One, or several, large or small joints were moderately or severely affected. Periarticular involvement was often more noticeable than intra-articular. Suppuration was not encountered. The appearance and roentgenograms of joints resembled those of atrophic arthritis. In all of these cases the characteristic diplostreptococcus of Bergen was isolated from intestines, and about 80 per cent of the animals injected intravenously therewith were found to have intestinal lesions strikingly like those of patients. However, arthritis was not produced in a single

animal (a significant fact in the face of the presumed case with which arthritis is produced in animals by streptococcal injections—Ed) This suggested that the articular lesion in man may result, not from metastatic invasion of the specific diplostreptococcus, but from related "toxins" or an unidentified secondary invader

Points which seemed to distinguish the arthritic entity were (1) the clinical relationship between the appearance, activity, and recovery from the colitis and the arthritis, (2) the greater tendency to periodicity and to more complete remissions (at least after earlier bouts) in the arthritis than is usually seen in atrophic arthritis, (3) the striking improvement that may occur in the joints from use of specific serum (antistreptococcic serum therapy for ordinary atrophic arthritis has generally been abandoned as useless), and (4) the fact that although certain streptococci can be isolated from various sites, including the intestines and stools of patients with atrophic arthritis there were certain cultural and physical differences between them and the diplostreptococci isolated in such cases

(The foregoing data are admittedly incomplete and inadequate for the establishment of a new entity Only a few cultures of synovial fluid or tissue have been made as hydrophilia was not a feature Cultures revealed no specific diplostreptococci Pathologic data are not yet presented Until more information is forthcoming the reader will probably prefer to assume that a coincident and more or less unrelated atrophic arthritis was present with colitis Those who glibly incriminate more or less symptomless intestines as the cause of atrophic arthritis should note the relative rarity of articular disease in the presence of severe ulcerating lesions of the intestines with blood, pus and multiple stools Arthritis complicates ulcerative colitis in only 4 per cent of cases, typhoid fever in 10 per cent or less, bacillary dysentery in about 3 per cent, and amebic colitis rarely if ever Those who "blame the bowels" may find some comfort in the evidence which shows that arthritis and intestinal diseases can be causally related [by hematogenous, not the enterogenous route], but the rarity of a proved relationship should give one pause

However, there is need for complete open-mindedness on this difficult problem As many now tend to incriminate symptomless infections of nasopharynx as foci for atrophic arthritis, so some argue that symptomless gastrointestinal infection or "faulty elimination" may play a significant role either as a primary or predisposing cause of arthritis—Ed)

RHEUMATIC FEVER

Predisposing Factors A few new data are available on predisposing factors geography and climate, seasonal influences, social and hygienic conditions, heredity, and the factors of age and sex

Relation of Geography and Climate to Incidence Further evidence is presented indicating that rheumatic fever is much less common in the southern than in the northern United States^{29, 157} The incidence diminishes progressively from latitude 50° to 29° (as it does also for scarlet fever but not for acute glomerulonephritis, a fact which is strange¹⁵⁷ if hemolytic streptococci are the cause of each of these diseases) The incidence of mitral stenosis in New Orleans (latitude north 29°) is one-twentieth that in Boston

(latitude north 42°)²⁰ Either there is much less rheumatic fever in the South or it does not affect the heart as it does in the North. The incidence of rheumatic carditis in two Dallas, Texas, hospitals (latitude north 32°) was low¹⁵⁸. Of 32,753 medical admissions to a hospital for private patients, 0.34 per cent (114) had rheumatic fever, of which 43 per cent had arthritis, 37 per cent tonsillitis. Only two patients had chorea. Of 10,800 medical admissions to a hospital for charity patients, 1.01 per cent (110) had rheumatic fever, of which 53 per cent had arthritis, 36 per cent tonsillitis. There were two cases of chorea. These figures indicate that rheumatic polyarthritis is less common, chorea much less common, in Texas than in the North.

Rheumatic fever is common in England and Scotland. On a given day in February 1935, there were 99 cases of rheumatic carditis in Edinburgh hospitals. In four large hospitals, one in 8 of all medical patients was suffering from rheumatic carditis (Ritchie¹⁵⁹). At Queen's Hospital, Birmingham, 4.3 per cent of the 5308 medical admissions between 1924 and 1928 were for rheumatic carditis; these cases formed a third of all admissions for cardiovascular diseases (Brenner¹⁶⁰).

According to Rogers (1924) and Clarke (1930), rheumatic fever and carditis are practically unknown in the tropics. New statistics refute these contentions. Cairns, Australia, a city of 13,000 people in latitude 17° south, a city well within the tropics, had 666 cases of acute rheumatism in 11 years (Cooper¹⁶¹). Mortality statistics from several Australian cities indicate that the severity of rheumatic fever varies with the latitude, becoming progressively greater as one goes from tropical (northern) Australia to the temperate (southern) portion. Usual manifestations of rheumatic fever were present in the cases of Wig¹⁶² in the Punjab (Lahore). According to Kutumbiah¹⁶³ 143 cases of rheumatic carditis were seen in three years at the King George Hospital, Vizagapatam, South India, latitude 16° to 20° north—wholly within the tropics. (The clinical data seem quite acceptable. No pathologic data were presented—Ed.) The report to McKinley³ from Sprawson, Director General of the Indian Medical Service, indicated that rheumatic fever was to be found generally throughout India. ("The approximate number of cases of rheumatic fever" is given at 276,611—which seems to include cases of "febrile endocarditis" and of "rheumatism". No further explanation is given, the figures cannot be interpreted—Ed.)

Seasonal Incidence As elsewhere so in Minneapolis, rheumatic fever in children most commonly appears during early spring (February to April) and late fall (October to December)¹⁶⁴.

Social and Hygienic Conditions Some think that the poorer the child the more likely he is to get rheumatism. Patients studied by Taran¹⁶⁵ all belonged to the poorest class of the community in Brooklyn, New York. Others think it is not the poorest, but the "decent poor," children of the respectable working classes, that are chiefly attacked¹⁶⁶. The cases of Preston¹⁶⁶ seemed to support this view. In English schools for poor children, rheumatic fever is common, in those for children of the upper classes it is

almost unknown. Eton, a school of 1,100 boys has had only one case in 17 years,¹⁶⁷ but in the town of Eton the elementary school children are frequently affected.¹⁶⁸

Factor of Heredity and Family Incidence Rheumatic fever is a familial disease. Whereas Shapiro¹⁶¹ found it in only 15 per cent of families of non-rheumatic children, he found it in 47 per cent of families of his rheumatic children, often several members of a family having been affected. Among 458 children with rheumatic carditis seen by Gilkey,¹⁶⁹ in the families of 105 children there were two cases, in the families of 20 children three cases, and in the families of 10 children four cases of rheumatic disease. Preston¹⁶⁶ found a familial incidence in 45 per cent of his cases of acute rheumatism with carditis. In his 200 cases Wilkinson¹⁶⁷ found a familial incidence of nearly 70 per cent. However, in a study of 24 patients less than three years of age with rheumatic fever McIntosh and Wood¹⁷⁰ found no simultaneous rheumatic fever in the home and felt that the frequency with which post-rheumatic infection had occurred in the parents of these children was no greater than one would expect to find in any family. (No control figures were given by McIntosh and Wood, however—Ed.)

Factor of Age Rheumatic fever and carditis generally first appear between the ages of six and 12 years as current statistics again show. Of Taran's¹⁶⁵ 169 patients, 88 per cent were from six to 12 years of age. The peak incidence of onset was between five and six years in Shapiro's cases,¹⁶¹ and between 11 and 15 in Ritchie's 244 cases.¹⁵⁹ Rheumatic fever may first appear at any time from birth to old age. Forty cases in infants less than a year old have been reported (Paul, 1932). Although rare under the age of three years, it probably occurs more frequently than is recognized. McIntosh and Wood¹⁷⁰ found references to 40 patients in the first three years of life. In the past 25 years at Babies Hospital, New York City, 24 cases of rheumatic fever affecting children less than three years old were seen. Necropsy was performed in six cases. The impression that rheumatic fever in infants is somewhat different than in older children was not definitely confirmed. Of children less than three years old, 96 per cent exhibited carditis, 46 per cent polyarthritis. However, the clinical picture was "more often that of a general infection than of a specific disease entity." "Several" of Shapiro's patients¹⁶¹ were less than two years of age.

The disease first appeared, once after the age of 50 years and once after the age of 60 in the cases of Davis and Weiss,¹⁷¹ occasionally after the age of 60 in those of De Graff, Lingg and Cohn.¹⁷² According to Ferris and Myers¹⁷³ when the disease begins in patients more than 60, it is similar to that in younger persons except that polyarthritis is possibly less intense and more persistent. Of six such patients, three died and the characteristic pathologic changes were found at necropsy. Carditis developed in the remaining cases. With appropriate data one should therefore not hesitate to

make a diagnosis of an initial attack of rheumatic fever simply because a patient is more than 50 or 60 years old

Factor of Sex Among children, rheumatic fever presumably affects girls more often than boys in a ratio of 6:4. Gilkey's patients¹⁶⁹ with rheumatic carditis included 275 girls, 183 boys. There were 142 females (62 per cent), 85 males (38 per cent) in the series of Brenner,¹⁶⁰ who stated that up to the age of 20 the incidence in males about equalled that in females. The preponderance of affected females begins only after the age of 20 years. Rheumatic carditis is thus less common but more severe in males and gives rise to symptoms earlier. However, in Taran's¹⁶⁵ group of 169 children were 85 girls, 84 boys. Of those with carditis, half were girls, half boys.

General Symptomatology The familiar and varied symptoms were again described^{159, 167, 170, 171, 175}. Many "growing pains" of children are not rheumatic. Differentiations of the rheumatic and non-rheumatic variety were recorded. Rheumatic growing pains, according to Shapiro¹⁶⁴ are commonly articular, affect joints of arms as well as legs, are generally better at night if the patient is warm, worse in daytime and on walking, particularly during the first hour of the day, are often associated with a little fever, articular swelling and heat, and with other signs of rheumatic activity: frequent nose-bleeds, pallor, undernourishment, fever, abdominal cramps and carditis. The non-rheumatic variety are not so generally articular, are usually diffusely and vaguely located in muscles of legs and thighs, appear or are worse at night soon after going to bed, may be gone in the morning, are not present on motion, produce no limping or significant stiffness during the day and are not associated with fever or other evidences of ill health. (Shapiro's differentiation suggests one between arthralgia and myalgia, not necessarily one between rheumatic and non-rheumatic types of pain —Ed.)

Rather than being better at night, rheumatic pains, according to Rosenblum,¹⁷⁶ may be particularly noticeable at night although they may occur at any time. Non-rheumatic pains in the limbs of the tired, weak child occur only in the legs, often only during or immediately after exercise, and disappear with rest. In case of doubt treatment with salicylates is suggested. "The pains of true rheumatism subside with adequate doses of salicylates."

(There is no reason why many non-rheumatic pains should not also be somewhat relieved by salicylates. The differentiation seems inadequate since the analgesic action of salicylates on rheumatic pain is only relatively, not absolutely, specific —Ed.)

Rheumatic growing pains may be muscular as well as articular, Preston stated¹⁶⁶. If muscles of calves, thighs or arms are definitely hard and painful to the touch, they should be considered rheumatic. Many non-rheumatic pains are produced in children by orthopedic defects, which Preston¹⁶⁶ and Elman¹⁷⁷ frequently found in supposedly "rheumatic children." These defects included flat feet, hammer toe, kyphoscoliosis, hallux valgus, hallux rigidus, genu valgum, and pes cavus.

The frequency of tonsillitis and upper respiratory infections as precursors of rheumatic fever has been noted by many. Among 458 rheumatic children Gilkey¹⁶⁹ noted that 70 per cent had had a preceding tonsillitis or recurrent sore throat, and 10 per cent recurrent colds. Respiratory infections occurred as a precursor in 42 per cent of the rheumatic infants in McIntosh and Wood's cases¹⁷⁰. The reports of Coburn and Pauli are well known, they have further reported¹⁷⁸ that of 17 patients whose throats became infected with an epidemic strain of a toxin-producing hemolytic streptococcus, 14 had a rheumatic exacerbation. Rheumatic fever was often, but by no means always, precipitated by respiratory infections in the cases studied by Bland and Jones¹⁷⁹ respiratory infections were noted in 75 per cent of those with recurrences. Less than 10 per cent of rheumatic attacks experienced by the patients of Wheeler, Ingerman, DuBois and Spock¹⁸⁰ were preceded within three weeks by respiratory infections.

(Variable opinions on the etiologic significance of prodromal respiratory infections will be discussed later under "etiology and pathogenesis"—Ed.)

Kutumbiah¹⁶³ noted that polyarthritis is not nearly as frequent a manifestation of rheumatic fever in children as in adults, at least in the tropics. Of his patients with juvenile rheumatic carditis only 18 per cent had polyarthritis.

Special Symptomatology and Pathology Cardiovascular. Last year (1935) was the centennial of Bouillaud's recognition of the connection between rheumatism and endocarditis. The course of rheumatic carditis has been again reviewed^{159, 165, 167, 171, 172}. In the large cities of the United States about 1.5 to 2 per cent of school children have some cardiac disability. Thus in Chicago about 10,000 children would be so affected¹⁷⁶. The annual mortality from rheumatic carditis in England is 12,000 to 30,000. Wilkinson¹⁷⁷ estimated that, in England, there are more than 50,000 children and not less than 100,000 adults with rheumatic carditis. Most rheumatic patients develop carditis, particularly infants. Of the latter seen by McIntosh and Wood,¹⁷⁰ 96 per cent had carditis. Newer statistics on the types of cardiac lesions present confirm previous reports^{160, 163, 165, 166, 170, 177}. For example, in Brenner's¹⁶⁰ 127 necropsies (with chronic valvulitis) the mitral valve was involved in 99 per cent, aortic in 66 per cent, tricuspid in 19 per cent and the pulmonary in none. According to Brenner, there are three types of cardiac involvement: (1) the acute type, running a fulminating, fatal course without time for chronic valvulitis to develop, (2) the subacute type, with repeated attacks and the development of valvulitis, (3) the chronic type, in which severe carditis never occurs but there are many minor attacks, often entirely overlooked, and in which mitral rather than aortic disease eventuates.

Rheumatic tricuspid stenosis is rare. Only 250 cases were reported up to 1933. A case observed by Clemens¹⁸¹ was unusual because the tricuspid ostium was extremely narrowed, symptoms were those of mitral stenosis, other valves were normal except for mitral insufficiency and slight mitral

valve sclerosis, and the right auricle was only slightly enlarged in spite of the extreme tricuspid stenosis

Aschoff bodies are rarely found in the myocardium during the first four weeks of the disease, thereafter, they are present in about 90 per cent of cases. An earlier lesion which some believe to be specific for rheumatic fever, may be found—the “fibrinoid degeneration” of Klinge. Chiari¹⁸² reviewed its structure: loosening of interstitial tissue, areas more strongly colored by eosin, and enlargement and irregular swelling of connective tissue fibers—at first with no alteration in nuclei and little or no surrounding cellular reaction. Chiari supported the view that the discovery of such lesions indicates the rheumatic nature of a condition even when Aschoff bodies are absent.

Points in the differentiation of functional and organic murmurs and congenital and acquired carditis were restated by Lyon^{171, 175} and by Dwan.¹⁸³ An apical systolic murmur, so often found in children, is of no significance unless there has been a recent attack of rheumatism or chorea or unless there is present cardiac dilatation, tachycardia or a lack of response to effort. Malmer's epinephrine test (1932), sound tracings, and microphonic amplification are recommended by Dwan to clarify murmurs.

With rheumatic carditis, pericarditis is not uncommon (about 17 per cent of Brenner's¹⁶⁰ cases). Eight of nine cases of rheumatic pericarditis seen by Antell¹⁸⁴ began during polyarthritis. Cardinal signs are friction rub, an enlarging heart outline, and certain alterations in the left thorax posteriorly: flatness and diminution of breath sounds at the left base, dullness, bronchial breathing, bronchophony and pectoriloquy at the angle of the left scapula. Electrocardiograms were of no aid to Antell in diagnosis. Rheumatic pericarditis alone is uncommon. Yater and Hedley¹⁸⁵ reported the case of a young woman with recurrent rheumatic fever who had pericarditis and septicemia with “alpha prime streptococci”. At necropsy, myocarditis and endocarditis were not found. The organisms, injected into monkeys and rabbits, produced arthritis and ulcero-vegetative endocarditis.

Blood vessels are widely affected in rheumatic fever, and Gross and his colleagues^{186, 187, 188} have continued their studies thereon. Varied lesions of the coronary and pulmonary arteries, aorta, and the left auricle were depicted in photomicrographs.

Lungs A clinical diagnosis of rheumatic pleurisy is not often made. The studies of Starr and Parrish¹⁸⁹ indicate that pleurisy is commoner than supposed, as can be demonstrated if routine roentgenograms of the chest are taken during the active phases of rheumatic fever. Interlobar pleural thickening was found in 44 per cent of children with other manifestations of rheumatic fever, it was found in 14 per cent of those with chorea alone but in only 9 per cent of “normal” children.

Nodules The subcutaneous rheumatic nodule is “perhaps the most characteristic single sign of acute rheumatism”¹⁶⁷. Nodules may appear about joints, especially elbows, knees, carpometacarpal joints, wrists, ankles,

and about the occiput or iliac crests. They vary in size "from a pin's head to an almond," generally that of a "split-pea." They may appear in great numbers or be scanty, especially in infants¹⁵⁹ (They were present in 14 per cent of Coburn's cases, 1931—Ed.) In India they are the rarest of all rheumatic manifestations¹⁶³. In Elman's¹⁷⁷ ambulatory cases of rheumatic carditis none were found. Several, unusually large painless nodules were found by Davison¹⁹⁰ in the occipital, iliac and sacral regions of an eight year old boy. After three weeks they receded.

Skin Erythema annulare rheumaticum, described by Lehdorff and Leimer (1922) is "a specific exanthem associated only with rheumatic endocarditis." It appears following endocarditis, never at the onset of acute fever. Transitory in nature, it is often overlooked. According to Lehdorff and Leimer it occurs in about two-thirds of cases of juvenile rheumatic endocarditis. Abt¹⁹¹ observed it in six children (more frequently than subcutaneous nodules). The lesions are pale red or bluish-red semicircles or rings one to three cm. in diameter. They are always macular, never papular, and disappear without scaling or pigmentation. They are found on chest, abdomen, back and thorax, rarely on extremities and never on the face or mucosae. There is no itching, edema or hemorrhage.

Exudates McEwen¹⁹² hoped to find in pleural, pericardial or synovial exudates in rheumatic fever the same characteristic cells which he found (1932) in rheumatic granuloma, however, they were absent. Sixty-two arthritic, eight pleural and five pericardial exudates from 33 patients with rheumatic fever were compared with 35 similar exudates from patients with other diseases. In rheumatic fever there were 800 to 47,000 leukocytes per cu. mm. of synovial fluid, depending on the severity of the arthritis. The cells were nonspecific in character, being similar to those of other exudates.

Routine Laboratory Data (Electrocardiograms, Sedimentation Rates, Blood Counts, Roentgenograms) Each of 63 cases of rheumatic fever seen by Master and Jaffe¹⁹³ demonstrated electrocardiographic abnormalities, "unequivocal signs of severe myocardial involvement." Common ones were RST changes (85 per cent), elongation of P-R interval over 0.2 seconds (53 per cent), T-wave inversion (40 per cent), isoelectric T-waves (29 per cent).

(Master and Jaffe did not emphasize sufficiently here or in their previous report (1932) that electrocardiographic alterations may not be seen if only one or two tracings are taken, and that to demonstrate abnormalities in 100 per cent of cases it was apparently necessary to take daily tracings—"as far as possible daily electrical tracings were taken." It is not stated how many single tracings were negative, how soon in relation to polyarthritis the tracings became abnormal, how often only minor abnormalities were present—ones which are sometimes seen in "normal" persons—or the average number of "negative tracings" necessary to be obtained before a case is considered electrocardiographically "negative." Our experience is that single electrocardiograms are frequently negative during the first, or an early, attack of polyarthritis and that in many cases repeated tracings are necessary to obtain some abnormality—Ed.)

Lead IV, according to Levy and Bruenn,¹⁹¹ sometimes furnishes evidence of active rheumatic carditis when changes are not observed in the standard three leads, or it may render significant the minor changes in these three leads which otherwise might be regarded as of doubtful importance. Most frequently observed changes in Lead IV were alterations in the direction or voltage of the T-wave.

According to Brenner¹⁹⁰ electrocardiograms are of little use in the diagnosis of chronic rheumatic carditis. Alterations may indicate that some sort of lesion is present, and where it is, but not whether it is rheumatic or not.

Brakeley¹⁹⁵ found that among 100 children with milder degrees of rheumatic carditis electrocardiograms differed little from those found in normal children or those with functional murmurs. They added no information not obtained by physical examination, although they did furnish confirmatory evidence. Important changes to look for in rheumatic carditis are an increased height and breadth of the P-wave, accompanied by notching, increase in the P-R interval, slurring or notching of the QRS complex, inversion of T-wave in two or more leads, and right axis deviation.

The average sedimentation rate at one hour was found by Orme¹⁹⁶ to be 70 mm.

(Westergren's modification of Fahraeus' test was used. Some consider this method too gross to be of value and favor the method of Rourke and Ernstene, 1930.—Ed.)

Leukocyte counts should be done in all cases. Leukemia in children may occasionally present symptoms resembling acute rheumatic fever.¹⁹⁷

Relation of Rheumatic Fever to Other Diseases—To chorea. The relationship between rheumatic fever and chorea will be discussed later under "chorea."

To atrophic arthritis. Some believe that rheumatic fever and atrophic arthritis are different diseases, others that they may be different manifestations of the same disease. Dawson¹⁹³ and Boots³⁴ favor the latter view. Similarities are that both show familial tendencies, seasonal incidences are essentially alike, respiratory infections may precipitate either, and subcutaneous nodules of essentially similar type are found in each. There are marked dissimilarities: the age incidences are very different, carditis is rare in atrophic arthritis, common in rheumatic fever. The latter is also characterized by erythemas and by response to salicylates absent in the former. In atrophic arthritis, agglutinins to hemolytic streptococci are present but antistreptolysins are absent, in rheumatic fever the opposite condition obtains.

As evidence of a close relationship Young and MacMahon¹⁹⁸ reported cases in which chronic atrophic arthritis followed what was presumably rheumatic fever and in which mitral disease was present. From a study of pathologic findings in other cases (not these cases) they concluded that articular tissues in either disease presented no definite differentiation.

(The report is open to criticism. Thirty cases were collected, but data on only 10 were tabulated and then so briefly that the reader cannot form his own conclusions. Only two case reports were given and these are inadequate for one to accept the diagnoses given. No roentgenograms, electrocardiographic reports, serologic differentiation or pathologic studies in these particular cases were given. The report seems premature in that no cardiac pathology was available to prove that the carditis was of the true rheumatic variety (with Aschoff bodies, etc.) or of a "nonspecific type." Patients with atrophic arthritis do occasionally develop a nonspecific carditis (Boas and Rifkin, 1924). Patients with atrophic arthritis frequently state that their disease started as an "acute rheumatic fever" or "inflammatory rheumatism." Practitioners are generous with these terms in any acute arthritis, forgetting that acute atrophic arthritis may occur. Careful questioning commonly reveals that acute atrophic arthritis, not acute rheumatic fever, initiated the chronic arthritis. Even were a patient to present pathologic evidence of rheumatic carditis and of atrophic arthritis, it could not be concluded that the two were part of the same disease. One could only conclude that the patient had both diseases, a state of affairs occasionally quite permissible by the law of coincidence or the chances for a double simultaneous infection.—Ed.)

SHAPIRO¹⁰⁴ believed that juvenile rheumatic fever has little if anything in common with chronic arthritis. "In the hundreds of cases of rheumatic infection which I have followed for the past 12 years I have never seen one instance where the patient developed chronic arthritis directly following juvenile rheumatism."

To subacute bacterial endocarditis. About 4 per cent of patients with rheumatic fever later succumb to bacterial endocarditis (White and Jones, 1928). The majority (50 to 65 per cent) of patients with subacute bacterial endocarditis have previously had rheumatic fever. Ideas as to the nature of this close relationship are that (1) rheumatic and bacterial endocarditis are reactions of different intensities to the same infection, or (2) subacute bacterial endocarditis is a secondary infection superimposed (a) on old or healed rheumatic valvular lesions, or (b) on recent or active rheumatic vegetations. From a study of 26 cases Von Glahn and Pappenheimer¹⁰⁹ concluded that bacterial endocarditis in rheumatic patients is due to the superficial implantations of non-hemolytic streptococci on active unhealed (not old) rheumatic vegetations. It is not the old scarred valve that is predisposed to subsequent infection with bacteria, but the valve or auricular wall affected by fresh, unhealed verrucae or plaques. Active rheumatic vegetations are a necessary prerequisite to bacterial implantation.

Differential Diagnosis. Rheumatic fever must frequently be differentiated from acute atrophic arthritis, acute polyarticular gout, or acute gonorrheal polyarthritis or polyarthralgia. Master and Jaffe¹⁰¹ compared electrocardiograms in 63 cases of rheumatic fever and 50 cases of acute atrophic arthritis. In those with rheumatic fever significant electrocardiographic abnormalities were found in 100 per cent (when daily tracings were taken). In those with acute atrophic arthritis there was a complete lack of electrocardiographic evidence of myocardial disease. Thus the presence of a definite abnormality in a given case would speak for rheumatic fever.

(Master and Jaffe have accepted the criticism that the presence or absence of an abnormal electrocardiogram may have influenced them in making a diagnosis of one or the other disease, and admitted a recent tendency to do this but believed that the differentiation was accurate none the less. Before one can establish the practical value of this differentiation further data should be forthcoming, particularly on how early in the disease and after about how many tracings the electrocardiographic abnormality becomes apparent. The paying patient of moderate means cannot afford many serial electrocardiograms, and, as mentioned before, single tracings are frequently negative in the early stage of acute rheumatic fever when differentiation is most desirable—Ed.)

The early polyarthritic or polyarthralgic phase of gonorrheal rheumatism is often mistaken for rheumatic fever. Furthermore, a patient with chronic gonorrheal urethritis may develop rheumatic fever, the latter being regarded as gonorrheal polyarthritis. In such cases Myers³⁰ and Boots³⁴ base differentiation on the electrocardiogram, a positive or negative salicylate effect, bacteriology and cytology of synovial fluid, and the gonorrheal complement-fixation test.

An initial attack of rheumatic fever may occur after the age of 50 or 60 years. However, the commonest form of acute arthritis in males more than 40 or 50 years of age is from gout, according to Hench^{40,106}. It is commonly misdiagnosed rheumatic fever. The stage of acute rheumatic polyarthritis is usually considerably longer (20 to 50 days) than that of gout (7 to 20 days). The diagnosis of rheumatic fever should not be dismissed simply because a patient is more than 50¹⁷³. Differentiation is made on electrocardiographic evidence, estimation of the blood uric acid, effects of salicylates or colchicine, and on the clinical course.

Course and Prognosis. The course and prognosis of rheumatic fever are almost entirely that of its cardiac component. The course is generally one of remissions and exacerbations, with occasional arrest, but usually with a more or less relentless progression. Exacerbations are so frequently precipitated by respiratory infections that some regard the latter not as non-specific precipitating factors but as an integral part (indeed the specific beginning) of either the first or subsequent attacks. Other factors, however, will provoke attacks: tonsillectomy, severe injuries, injections of typhoid vaccine, or an abdominal or other operation²⁰⁰. Bland and Jones¹⁷⁹ noted an initial, generally a subsequent, attack after tonsillectomy, appendectomy, or arthrodesis. Intravenous injections of typhoid bacilli have been used in the treatment of the disease. To study the effect, Bland and Jones gave a total of 12 such injections to 10 patients. In six cases an exacerbation appeared immediately or within three weeks. In two cases there was a doubtful, in four no, reaction. No serious effects were noted. Following the reactions "there seemed to be a more rapid progression to quiescent rheumatic fever than was previously noted." Studying the immunity mechanism, Coburn and Pauli¹⁷⁸ performed splenectomy on 20 children with quiescent rheumatic fever, in nine of these 20 cases recrudescences developed as a direct sequel to splenectomy, none died.

Effect of Pregnancy With others Willius²⁰¹ believed that in many cases of rheumatic carditis the stresses of the latter months of pregnancy, of actual labor and those incident to the subsequent physical care of the infant may precipitate cardiac decompensation. However, trouble does not always develop. Of 38 rheumatic women seen by Brenner¹⁶⁰ 15 had no trouble with repeated pregnancies up to 10. Four had no trouble with one or more early pregnancies, but heart failure developed after later pregnancies. In 19 cases heart failure began or became worse in the first pregnancy, four patients died within a few weeks of delivery.

Evidences of Activity or Reactivity The following are considered evidences of activity of the disease: the usual clinical evidence of slight persistent fever, tachycardia, joint pains, nodules, persistent underweight, pallor, unexplained abdominal pain, nosebleeds, tendency to vomit, leukocytosis, lassitude, an increased sedimentation rate, and electrocardiographic alterations.^{164, 176, 202-203} The disease may be active, however, without fever. If in the absence of fever the sleeping pulse rate is about the same as "the alert rate" (when the child is awake), activity can generally be presumed. A recrudescence is often evidenced by gradual quickening of both sleeping and alert pulse rates. On the other hand, if a drop of 10 to 20 beats per minute during sleep is noted, a rapid alert rate is probably of nervous origin.¹⁷⁶

Recurrences Of Shapiro's¹⁶⁴ 342 patients, 52 per cent had only one attack within the period of study (12 years or less), 48 per cent had one or more recurrences. Of the latter, 27 per cent had them within one year, 54 per cent within two years, 70 per cent within three years, and practically all within nine years. Of Gilkey's¹⁶⁹ 458 patients, 49 per cent had recurrences within three years. Of Preston's¹⁶⁶ 157 patients with carditis 30 per cent had one attack only, 38 per cent had one relapse, 32 per cent had two or more relapses. Of those without carditis, 70 per cent had one attack, 24 per cent had one relapse, 6 per cent two or more.

End Results The course of rheumatic carditis has been outlined by De Giuff and Lingg¹⁷² who studied 644 patients who died of it. Fifty-six per cent were males, 44 per cent females. Rheumatic carditis usually existed alone (95 per cent of cases), was seldom combined with other etiologic types (5 per cent). The average patient is infected at the age of 17 years, but will be free of symptoms and able to carry on ordinary physical activity for 11 years. He will then begin to suffer from diminished cardiac reserve, culminating in heart failure two years later. From this time until his death, three years later, he is wholly an invalid, or at least in most cases is seriously incapacitated. The period of economic usefulness of a rheumatic victim is generally less than nine, not more than 11, years after the initial rheumatic infection. Once symptoms of cardiac insufficiency appear, heart failure and death rapidly ensue. Fifty per cent suffer their first symptoms and failure and die within a period of from 16 to 20 years after initial infection (or

between 20 and 40 years of age) To see even terminal stages of the disease in patients more than 50 years of age is uncommon Death usually occurs from heart failure, but life is shortened in some cases by subacute bacterial endocarditis, pneumonia and other diseases Of the 644 patients in De Graff and Lingg's series, 43 per cent developed auricular fibrillation, but this did not per se determine prognosis on life expectancy When fibrillation, a late manifestation, set in, the die was already cast The incidence of the various valvular lesions was given Mitral disease was more frequent in women, aortic disease in men The location or number of valves affected did not seem to influence the duration of life except in the case of pulmonic or tricuspid valves then the prognosis was less favorable

A similar study of 113 cases was made by Davis and Weiss¹⁷¹ After the onset of the disease, the patients lived from a few weeks to 40 years About 50 per cent lived less than six years about 50 per cent lived from six to 25 years

Etiology and Pathogenesis Arguments on various theories are essentially similar to those reported in previous Reviews

Infectious Theory Evidence supporting this theory is direct and indirect Presumably direct evidence is that from cultures of the blood, nasopharynx and other tissues Blood cultures by McIntosh and Wood¹⁷⁰ were negative in six cases, positive for non-hemolytic streptococci in one As already noted, the frequency with which tonsillar or upper respiratory infection occurs as a precursor of rheumatic fever has again been demonstrated by Coburn and Paul,¹⁷⁸ Gilkey¹⁶⁹ and McIntosh and Wood¹⁷⁰ The significance of this prodromal infection is debated In Bland and Jones' series¹⁷⁹ of "over 1,200" rheumatic children and adolescents, respiratory infections were experienced by 75 per cent of those with recurrences However, many exacerbations occurred without preceding respiratory infections and recurrences were frequently precipitated by other and nonspecific factors such as accidents, abdominal operations, or injections of typhoid vaccine Bland and Jones therefore concluded that the bacteria causing respiratory infections may not be as specifically related to the disease as some believed, but may be of secondary importance

Of rheumatic attacks among 222 patients of Wheeler, Ingerman, DuBois and Spock¹⁸⁰ less than 10 per cent were preceded within three weeks by a respiratory infection When such infections did develop, only 16 per cent of them produced rheumatic activity Practically all of another group of 123 patients suffered respiratory attacks on an average of five each Although 54 per cent of these infections were with hemolytic streptococci, 84 per cent were not associated with rheumatic activation A comparison of 4867 throat cultures from 123 rheumatic, and of 1231 cultures from 109 nonrheumatic, children by Wheeler, Wilson and Leask²⁰⁴ showed no significant difference in the frequency or in the appearance time of hemolytic streptococci and no noteworthy difference in the incidence of such organisms

in throats during apparent health, upper respiratory infections or rheumatic activity. These authors concluded that an etiologic relationship between rheumatic fever and respiratory infections with hemolytic streptococci was not evident.

This conclusion is at variance with that of Coburn and Pauli¹⁷⁸ who distinguished between respiratory infections with non-toxin producing hemolytic streptococci, ineffective in provoking rheumatic exacerbations, and those with a strong, skin toxin-producing hemolytic streptococcus capable of activating rheumatic processes. In the winter of 1934, the throats of a group of rheumatic children were infected with the former type—a non-toxin producer—in none did an exacerbation develop, nor did any during a subsequent influenzal epidemic. Soon thereafter these same children were exposed to an epidemic of a toxin-producing hemolytic streptococcus of a single type. Of 16 rheumatic children thus affected, 14 had acute rheumatism, two escaped. The 14 affected patients developed increased antistreptolysins with the onset of symptoms. The two who were definitely infected with the same toxin-producer but escaped a rheumatic exacerbation did not develop antibody (antistreptolysin) response. Seven rheumatic children did not contract the toxin-producing streptococcal infection, thus indicating that some susceptible persons may live in close association with an epidemic of acute rheumatism, develop no rise in antistreptolysins and maintain excellent health. An additional patient, one with congenital heart disease, did become infected with the “effective strain” and did develop a typical antibody response, yet this patient escaped rheumatic manifestations, indicating that more than a bacterium is responsible for the disease. Cultural characteristics of the effective and non-effective strains were essentially similar, but the effective strain was capable of producing strong skin toxins and streptolysins and was indistinguishable from scarlatinal strains of hemolytic streptococci.

Indirect evidence for the infectious theory is derived from skin tests, and tests for streptococcal agglutinins, antistreptolysins, streptococcal complement, antistreptolysins and precipitins. *Skin tests* with hemolytic streptococci were “positive” in 80 per cent of Gilkey’s¹⁶⁹ 458 rheumatic children and in 20 per cent of controls, and in 75 per cent of Kaiser and Keith’s²⁰⁰ 200 rheumatic children and in 32 per cent of their non-rheumatics. They were also positive, however, in a fairly high percentage of patients with other streptococcal infections.

Agglutinins Blair and Hallman²⁰⁰ found a somewhat larger percentage of high agglutinin titers with serums from cases of rheumatic fever than has been reported by others. Twenty-five serums from 24 patients were tested agglutinins to Cecil’s typical strains of hemolytic streptococci AB 66 (from a patient with atrophic arthritis) and Q 33 (from a patient with rheumatic fever) were found in dilutions of 1:160 or more in 14 serums. Only one patient with rheumatic fever had agglutinins (1:40) to *Streptococcus viridans*.

The *streptococcal complement-fixation test* was positive in varying degrees in Coburn and Pauli's active cases of rheumatic fever (1932), but was only occasionally positive (sometimes strongly) in quiescent cases. Beck and Coste²⁰⁷ found the test positive for only seven of 79 patients with various types of rheumatism or arthritis, presumably streptococcal. It was positive in two of four cases of rheumatic fever, but also often positive in cases of pregnancy and of tuberculosis.

Antifibrinolysins Broth cultures of hemolytic streptococci (but not of other organisms) of human origin rapidly liquefy the fibrin clot of normal human plasma. In patients convalescent from acute hemolytic streptococcal infections (and rheumatic fever) the fibrin clot is highly resistant to this fibrin-lysis owing to the presence of a substance (antibody) called "antifibrinolysin." Although certain amounts of antifibrinolysin are found in the plasma of normal persons and those without evidence of recent hemolytic streptococcal infection, Myers, Keefer and Holmes²⁰⁸ found much greater amounts in plasma of patients with erysipelas and other acute hemolytic streptococcal infections and with rheumatic fever. (However, antifibrinolysins were not found in cases of atrophic arthritis—Ed.)

Precipitins Extending previous work (Coburn and Pauli, 1932, Schlesinger and Signy, 1933) Schlesinger, Signy and Payne²⁰⁹ demonstrated precipitins to hemolytic streptococci in the blood of non-rheumatic patients with recent tonsillitis, but in greater amounts in that of rheumatics. Precipitins are practically absent in cases of quiescent rheumatic fever, in rheumatic patients, they generally appear between the tenth to thirtieth day after the acute throat infection. Just at this time rheumatic relapses commence. Apparently when immune responses are at their height, the patient's tissues seem to possess a vulnerability that perhaps allows an as yet undiscovered cause of rheumatic fever, perhaps a virus, to enter the body or, having already entered, to become active.

Antistreptolysins * The normal level of antistreptolysins is from about 50 units¹⁷⁸ to 100 units²⁰⁶. Blair and Hallman²⁰⁶ found increased antistreptolysins in 15 of 18 rheumatic patients. The disease was "inactive" in the three whose titers were normal. Coburn and Pauli¹⁷⁸ found a marked increase in antistreptolysins (to an average of about 500 units) in rheumatic patients infected by the "effective strain" of hemolytic streptococcus, the increase was coincident with onset of symptoms of rheumatic activity. Unless such a rise appeared, no rheumatic exacerbation was experienced. Apropos of the reported rarity of rheumatic fever in the South as compared to the North, Coburn and Pauli²¹⁰ found that high antistreptolysin titers are more prevalent in latitudes over 40° than in those below 35°. However,

* Coburn, Wilson and their colleagues use the terms "antihemolysin" and "antistreptolysin" synonymously, but prefer the term "antistreptolysin" which emphasizes the relation of the antibody to streptococci.²¹² To be absolutely correct one should use the term "antistreptohemolysin." The antigen, streptolysin, is a soluble product of hemolytic streptococci which hemolyzes erythrocytes. The antibody, antistreptohemolysin or "antistreptolysin," neutralizes the antigen streptolysin, one titrates with streptolysin to determine the presence and titer of "antistreptolysin"—Ed.

the work of these investigators is again at variance with that of their fellow townsmen, Wilson, Wheeler and Leask²¹¹ The latter made clinical, bacteriologic and immunologic studies on 80 rheumatic subjects over a period of 12 to 18 months The average antistreptolysin value was 135 units for those with inactive disease, the range was 25 to 715 units The range among patients with inactive or active rheumatism or with respiratory infections was about the same Those with respiratory infections unassociated with hemolytic streptococci showed a higher average titer and a greater rise than those with hemolytic streptococcal respiratory infections An increased titer therefore does not necessarily indicate a hemolytic streptococcal infection Rheumatic activity developed in many cases without preliminary respiratory infection two-thirds of them had no rise in antistreptolysin titer A rise in antistreptolysins is therefore not a necessary accompaniment of rheumatic fever Increased antistreptolysins seemed directly related to the extent of the local and constitutional symptoms of the respiratory infection, irrespective of the presence of hemolytic streptococci and bore no relation to the clinical course of rheumatic activity

Interpretation of Immunologic Data (The work of the Columbia group seems to be in sharp contrast with that of the Cornell group The writings of the former seem to us easier to follow, although the work of both groups appears to have been done very carefully and exhaustively It was impossible for us to interpret these immune responses or to harmonize the conflicting views In an attempt to do so the editors wrote Drs Wilson, Coburn and Pauli A possible explanation was offered by Dr Wilson She and her colleagues included non-rheumatic children among their controls Coburn and Pauli apparently did not Antistreptolysin values for babies approximate those for adults, but those for children may not Because children are so susceptible to respiratory infections they may, even after minimal infections, have values higher than adults or babies Rheumatic fever in childhood may be an entity not entirely comparable to that in adults A further factor may have been the selection of cases for study there may have been less selection of those of Wilson and her colleagues who included records of all cases seen in a specified time Since high antistreptolysin titers were noted in patients who did not develop rheumatic exacerbations Wilson was inclined to doubt the importance of a special, potent strain of hemolytic streptococcus Obviously, final interpretation must await more data thereon However, the preliminary interpretation of Coburn and Pauli¹⁷⁶ is given—Ed)

Three factors seem to be necessary for the production of a rheumatic attack (1) infection, not just with any hemolytic streptococcus but with a highly effective agent—a strong soluble-toxin producing hemolytic streptococcus, (2) a disease pattern peculiar to each rheumatic subject, (3) an intense immune response as indicated by a rise in antistreptolysins A patient can be infected with an "effective strain," but unless a marked antibody response develops, a rheumatic exacerbation does not ensue Therefore, the character of the antibody response plays a large part in determining whether an attack will follow If the patient's antibody-producing tissue is quiescent when the hemolytic streptococci or other precipitating agent acts (for example, an operation such as splenectomy), no rheumatic exacerbation ensues If the antibody-producing tissue is in a state of activity at that

time, an exacerbation may result (To this extent, then, the patient is as much, if not more, the cause of the disease than the invading substance—Ed) Thus the pathogenesis of rheumatic fever is presumably as follows (1) the toxin-producing hemolytic streptococcus initiates a process peculiar to rheumatic subjects, (2) in the course of the process a substance is released presumably from the antibody-producing tissues, which directly or indirectly alters mesodermal structures, this substance is probably not the infecting organism, and at present there is no evidence to suggest that it is viable, and (3) the release of this toxic substance seems to occur only when there is an immune response to hemolytic streptococci

Coburn and Paul's idea of a more or less specific sensitivity or allergy, a peculiar antigen-antibody reaction involving a special type of hemolytic streptococcus, is in contrast with that of Swift²⁰ and others that rheumatic fever results from a hypersensitivity to a wide range of streptococci or other bacteria. The idea of a broad streptococcal allergy is accepted by many^{1,9,160,213,214,215}. In support of the allergic theory various tissue reactions, including some resembling those of rheumatic fever, were produced by Chiari¹⁸² in animals given allyl-formiate, by Baker, Thomas and Penick²¹⁶ in animals sensitized to beta hemolytic streptococci, and by Andrieu and Ravennà²¹⁷ in animals sensitized to arthrotropic streptococci. However, not all of the animals presented these reactions, and many of the reactions were considered quite nonspecific, unlike the lesions of rheumatic fever.

Objections to the idea that the disease represents general allergy have been raised by Stuart-Harris²¹⁸ and by Sayle²¹⁹. Objections are that (1) the percentage of skin reactions to hemolytic streptococci is no greater in rheumatic than in control groups, and is much less than in scarlet fever, (2) skin reactions to non-hemolytic streptococci are present in rheumatic fever but also in controls, (3) there are many diseases due to hemolytic streptococci and other organisms, to which candidates for rheumatic fever should be sensitive, which are not associated with rheumatic-like manifestations, (4) certain "skin-positive rheumatic patients" with hemolytic streptococci in their throats escape relapses, and (5) in artificial sensitization, the silent period between resensitization and symptoms becomes less and less, in rheumatic fever it remains about the same in spite of repeated exacerbations.

The frankest objections are those of Freeman,²²⁰ who criticized the whole idea of bacterial allergy in rheumatism, particularly the chronic types. In the first place "allergy" is at present a non-definable term, even authorities being troubled by its ambiguity and the difficulty of using it with precision. The types of streptococci, the germs presumably most concerned with bacterial allergy in rheumatism, are not yet satisfactorily classified. Skin tests afford little or no assistance and are quite inadmissible as evidence for "allergy" because their results are so inconclusive. In rheumatism the reactions vary greatly in intensity and time of appearance (four hours to four

days) They do not appear after five to 10 minutes as do the characteristic "wheal" reactions of "allergic diseases" like hay fever. Reactions may also occur in non-rheumatic persons and are not characteristic either of the disease under study or even of the organisms used therefor. Various immunologic reactions reported are not clear-cut because the antigenic properties of the responsible streptococci are adaptable, not fixed. One must strictly differentiate between (1) a specific infectious disease with allergic phenomena (as in tuberculosis), and (2) an "allergic disease" of the sort usually characterized by paroxysmal attacks, as in asthma, hay fever, etc. Aschoff would say, allergic phenomena are present in rheumatism, but rheumatism is not an allergic disease. This does not help us, however, to understand rheumatism. "The use of the word, 'allergy' will help only in so far as it emphasizes the action of the dissolved products of invading microorganisms (rather than the whole organism itself) and the necessity for immunization and desensitization."

We are inclined to believe that so beautiful a word as allergy must mean something important without concerning ourselves too much as to what that something may be. We are working in a fog and have as yet no clear vision. The word allergy is, to my mind, not a gleam of sunshine breaking through, but an extra wisp of fog."

Virus Theory In some ways rheumatic fever resembles a virus disease (Sayle²¹⁹). In certain diseases the virus apparently enters the body via the nasopharynx, a nasopharyngitis precedes rheumatic fever. Some virus diseases predispose to recurrences, which is the case in rheumatic fever. Virus diseases generally have a long incubation period (nine to 24 days), the "silent period" in rheumatic fever is about 10 to 21 days. Viruses are difficult to grow and are generally ultramicroscopic, were a virus responsible for rheumatic fever, current failures to grow or see it could be explained. In some virus diseases intracellular inclusion bodies are demonstrable, they have not been found in rheumatic fever, although granules of an unknown nature have been found within tissues by certain stains.

Schlesinger, Signy and Amies²²¹ isolated from the pericardial fluid of seven patients and from the pleural exudate of one patient particles which resembled virus elementary bodies. Suspensions of these bodies were specifically agglutinated by serums of patients with active rheumatic fever, but were not agglutinated by that of normals or of patients with inactive rheumatic fever or with various non-rheumatic infections. Coles²²² recovered similar "virus-like bodies" from pericardium and pericardial exudate of a victim of rheumatic fever (also from synovial fluid in four cases of atrophic arthritis).

(Proof of the significance of these bodies lies in the reproduction of the disease when they are injected into animals. This has not been done by any of these workers.—Ed.)

Theory of Nonspecific Infection Plus Vitamin C Deficiency Supplementing work with Mettliher and Connor (1934), Rinehart²²³ presented fur-

ther work in support of his idea that rheumatic fever may be the result of the combined influence of deficiency in vitamin C and infection. In guinea-pigs on a diet devoid of vitamin C which were inoculated with a guinea-pig strain of hemolytic streptococcus or other organisms, cardiac and articular lesions, and occasionally subcutaneous nodules, notably resembling those of rheumatic fever, developed with considerable frequency. Guinea-pigs infected with these organisms but on an adequate diet did not show such lesions, and those treated with a deficient diet alone showed only slight lesions. Swift²⁹ agreed that lesions of some sort were thus experimentally produced, but thought they were scorbutic, not rheumatic. He and his colleagues²²⁴ found no difference between rheumatic and non-rheumatic patients in the metabolism of vitamin C. Patients with active and quiescent rheumatic fever were treated with cevitic acid (concentrated vitamin C). The course of the disease was uninfluenced. Faulkner²²⁵ also noted no definite effect from feeding a high-vitamin C diet in 27 cases of rheumatic fever.

Perry²²⁶ applied the Harris-Ray test for vitamin C deficiency (urinary excretion of ascorbic acid after the administration of a test dose of vitamin C) to five patients with active and six with quiescent rheumatic carditis. Two of the former and three of the latter gave evidences of a mild vitamin C deficiency. However, the capillary resistance test was normal in all five. It was concluded that mild degrees of vitamin C deficiency are not uncommon in rheumatic children but are not important in the etiology of acute rheumatism.

Warner, Winterton and Clark¹⁶⁸ found a much higher consumption of fresh fruits and vegetables by rheumatic children and their families than by children in institutions in which there was a very low incidence of rheumatism. Although the consumption of animal protein and dairy products was low and that of carbohydrates high in the rheumatic group, no one dietary factor could be found as a contributory cause for the disease. Extra feedings with vitamins A and D proved of little value.

Treatment—For the general disease. Ritchie¹⁵⁹ ascribed no curative value to any serum, vaccine or medicine, including salicylates. The majority ascribe to salicylates only an analgesic effect, and no power to prevent or modify carditis. Citing reports on their ineffectiveness in preventing carditis and on their occasional toxic effects, Apfel²²⁷ stated that the use of salicylates is continued "simply because it has been handed down to us and we don't know what better to use." That salicylates are a specific is a "pernicious doctrine," according to Eason²²⁸ who considers doses now used sometimes dangerous. Others do not approve "the current fashion of belittling the use of salicylates." Antell¹⁸⁴ still regards them as "the sheet anchor" of treatment, even if they are not specific and are only analgesic. He prescribes them in large, "almost toxic" doses for children, 60 to 120 grains in 24 hours with sodium bicarbonate. Taussig²⁰² prefers aspirin.

to sodium salicylates, considers 30 to 45 grains daily sufficient, and 10 grains of salicylate per 10 pounds of body weight as a maximal daily dose for most children. Wilkinson¹⁶⁷ and Lyon^{174, 175} believed that inadequate doses are generally given and that, when enough is used, the drug does definitely prevent or modify the carditis in some cases. To prevent acidosis Lyon prefers "salicionol," an alkalized salicylate.

Replacing salicylates, amidopyrine is favored by Apfel,²²⁷ neocinchophen (tolysin) by Poynton.²²⁹ Fraser²¹⁰ saw an instance of fatal cinchophen poisoning in a case of rheumatic fever. Slocumb⁹⁹ reported the use by Frazer and Walsh²³¹ of intravenous injections of olive oil, reduction of fever and "adsorption of toxins by the minute fat globules" were presumably obtained. (Laboratory studies had not yet been carried out. The work has not been fully reported—Ed.) With similar intent St. Jacques²³² gave colloidal charcoal intravenously. (The data are very meager. No conclusions can be drawn—Ed.) When the hemoglobin fell below 50 per cent, Lyon^{174, 175} gave periodic transfusions of 100 to 200 c c of blood.

Extra vitamin C was given by Rinehart²⁻³ who was encouraged by preliminary results. However, no specific effect from vitamin C (530 c c of orange juice, or 200 to 300 mg in crystalline form) daily for four weeks was noted by Faulkner.²²⁵ The use of vitamins A and D "radiostoleum" appeared of little value to others.¹⁶⁸

Tonsillectomy Opinions on the value of tonsillectomy still differ. The majority favor early tonsillectomy if the tonsils are definitely diseased, but believe it should be done only when the disease is relatively inactive.^{159, 160, 167, 169, 203, 227, 229, 233} otherwise, an exacerbation may be precipitated. If the disease's activity is unusually persistent, tonsillectomy may have to be done while activity is present. (According to Robey, 1932, tonsillectomy even during activity of the disease can generally be done with safety and may be necessary if such activity is prolonged—Ed.) As a prophylactic Lyon¹⁷⁵ advised salicylate therapy for 10 days before and after tonsillectomy. Some favor tonsillectomy on suspicion in all cases, even when tonsils are not obviously infected. Tonsillectomy does not prevent rheumatic fever, which may result from pharyngitis in a tonsillectomized child, but a clean throat will diminish a predisposition to upper respiratory infections. According to the large statistics of Kaiser,²⁹ the child who has had his tonsils out is less likely to have rheumatic manifestations, and if he does have them serious cardiac complications are less likely to develop. Although the incidence of recurrent attacks was not influenced by tonsillectomy, the mortality among 600 children was about twice as high in those who had tonsils at the time of the initial attack as in those whose tonsils had been removed. Gilkey¹⁶⁹ likewise found a 50 per cent lower mortality rate among those whose tonsils were out before the first attack. Preston,¹⁶⁶ however, found only a slight advantage for the tonsillectomized child.

Vaccines, Antitoxin Attempts at desensitization by streptococcal vac-

cines and filtriates seemed worth-while to some,^{169 207} useless to others¹⁷⁶ Streptococcal antitoxin (scarlatina) was used by Eason²²⁸ in 37 cases, in 73 per cent "complete recovery" ensued after the use of 30 c c twice, 36 hours apart. Further doses had to be given to 27 per cent of the patients. Improvement began within 24 hours of the two initial doses. A brief febrile reaction usually preceded improvement. Serum rash and fever for one to two days later appeared in 32 cases. One patient died probably from a serum effect. Two of three control patients treated with normal horse serum also recovered. Because a few of the patients were relieved without developing febrile reactions, Eason believed that results were not entirely due to a foreign protein effect. No conclusions on the prevention of carditis were given.

(The use of three controls was insufficient. Foreign protein reactions may not need to be febrile to be effective. To date we would conclude that this "antitoxin method" gave nonspecific results, due to a foreign protein reaction—Ed.)

Using scarlatinal toxin Coburn and Pauli¹⁷⁸ attempted active immunization of 113 normal persons. Skin reactions to streptococcal toxin were markedly diminished thereby, but there was no evidence that this treatment increased resistance to streptococcal infections or prevented rheumatic fever. Ten patients with quiescent rheumatic disease were given "passive immunization" with antitoxin (antistreptococcal serum). The introduction of these protective antibodies just prior to an expected attack (just after a streptococcal infection) did not decrease, and possibly increased, the intensity of the rheumatic recrudescence.

Fever Therapy with Typhoid Vaccine or Radiant Energy Typhoid vaccine intravenously should be tried when salicylates fail, according to Cecil²³⁴, acute febrile polyarthritis may be thereby aborted. Although reactions to such vaccine, given when the disease is relatively inactive, may provoke a mild exacerbation, the disease thereafter may become more rapidly quiescent, according to Bland and Jones¹⁷⁹.

Fever therapy was given by Sutton and Dodge²³⁵ to 18 patients with active carditis. In 16 (who also had chorea) fever was produced by typhoid vaccine reactions, in two by radiant energy. From four to 14 fever sessions were given over a period of five to 26 days. In all cases clinical signs of activity of carditis completely subsided within 10 to 14 days after treatment. However, in some cases, relapses occurred after several months. The conclusions were that such fever therapy did not harm patients with sub-acute or inactive rheumatic carditis, it seemed to benefit them and deserved further study.

(The period of observation, about two years, was too short to permit final conclusions on the permanency of the effect. Further study is also required to confirm the apparently good immediate effects—Ed.)

Splenectomy did not favorably modify the course of the disease¹⁷⁸

For Joints Rest and salicylates continue as standard therapy Splints properly applied are far superior to salicylates (Apfel²²⁷)

For the Heart There are three objectives (1) immediate relief of symptoms, (2) restitution of cardiac reserve to the greatest degree possible, and (3) maintenance of cardiac efficiency after the patient is up and about by a carefully planned and individualized regimen Indications for digitalis, quinine, and salyrgan or other diuretics have again been given^{174, 175, 200-202} The minutiae of a "cardiac regimen" are clearly set forth in several short readable papers which particularized the time for renewal of activity of the convalescent patient, the plan of graded activity and the method for recognizing the changing functional status of the heart^{176, 200, 202, 236} The physiologic effect of light muscle training was carefully studied by Proger and Korth²³⁷ The establishment of convalescent "hospital-schools" and cardiac camps has made much more effective the care of convalescent children^{176 238}

To lessen cardiac strain and to prevent disaster in cases in which patients become pregnant, cesarian section under local or spinal anesthesia,²⁰¹ or induction of premature labor,¹⁶⁰ may be indicated

For pericardial effusions Antell¹⁸¹ preferred the use of oxygen tents for two to four days rather than paracentesis

Prophylaxis The prevention of the initial attack as well as of exacerbations depends at present on the fullest maintenance of a "physiologic life"¹⁵⁹ This necessitates the education of civic authorities to the value of smokeless, sunny cities with no overcrowding and with well-built homes, and the education of parents in "the wise nurture of children" with high resistance to disease—the prescription for which is good food, a proper ratio of rest and exercise, sunshine, frequent baths with contrast douches, the use of porous, light warm clothing, the removal of infected foci, and above all, the avoidance of respiratory infections by shunning crowds in unseasonable weather, and perhaps by the use of vaccines for children with repeated colds^{167, 203 239} Particularly desirable for children are long stays in semi-tropical or tropical climates

SYDENHAM'S CHOREA

Chorea may occur alone or with other manifestations of rheumatic fever, chiefly arthritis and endocarditis Some consider it a disease in itself, others regard it as a symptom of rheumatic fever^{240, 241} Still others believe it may be a symptom of several diseases²⁴² The close relationship of chorea and rheumatic fever is often very apparent Considering chorea a single manifestation of rheumatic fever, Jones and Bland (Boston)²⁴¹ found that of 1000 cases of rheumatic fever, nearly 50 per cent (482) had frank chorea, the rest had other symptoms of rheumatic fever without chorea Of the 482 that had chorea, 28 per cent had chorea alone, 72 per cent also had other symptoms of rheumatic fever In the South chorea is rare Of 224 pa-

tients with rheumatic carditis in Dallas, Texas, only four had chorea¹⁷⁸ Choreia is considered a "white man's disease," rare in American Indians and negroes²¹³ and in the tropics. However, Kutumbiah¹⁶³ and Wig¹⁶² noted several typical cases in India.

If chorea is a separate disease from rheumatic fever, according to Schwartz and Leader²¹⁰ one should expect the end of choreiform motions to signify the end of the disease, but if it is part of rheumatic fever, one may expect proof in the form of associated or subsequent carditis. Because in practically all of their 75 cases of "pure chorea" (no history and no evidence of rheumatic fever) carditis (myocarditis and mitral valvulitis) eventually developed within seven to eight years, Schwartz and Leader concluded that chorea is a symptom of rheumatic fever and that here also "the heart is always involved." In most cases the carditis developed insidiously, often without other attacks of chorea. In no case did aortic valvulitis, pericarditis or subcutaneous nodules develop.

These findings are in sharp disagreement with those of Jones and Bland²⁴¹. Carditis developed in only 3 per cent of 134 cases of "pure chorea," those without other symptoms of rheumatic fever, the mortality was 0.7 per cent. In contrast, carditis developed in 86 per cent of 518 cases of rheumatic fever without chorea, the mortality was 32 per cent. It developed in 80 per cent of 184 cases of chorea which preceded other evidences of rheumatic fever, and in 60 per cent of 164 cases of chorea which followed other symptoms of rheumatic fever. The presence or number of attacks of chorea apparently did not influence the development of carditis. Thus Jones and Bland regarded "pure chorea" as a mild manifestation of rheumatic fever, one of good prognostic import but one in itself not especially conducive to carditis.

From a study of 150 cases Geistley, Wile, Falstein and Gayle²⁴² concluded that chorea is not a disease but a symptom, more frequently of psychic trauma than of rheumatism. In their cases little relation to previous infection was found and no clinical evidence (no fever, leukocytosis, or increased sedimentation rate) of acute infection. Only 12 patients showed persistent signs of carditis. That other insults than rheumatism can cause chorea is also the suggestion of Hewins²⁴⁴ who noted a case with neurosyphilis, of Lewis and Minski²⁴⁵ who noted four cases with psychoses, and of Brian and Gerundo²⁴⁶ who noted a fatal case of chorea gravidarum and concluded that, in pregnancy, one may encounter the Sydenham (rheumatic) variety or another type, a symptom of toxemia of pregnancy.

Treatment Usual recommendations are rest and quiet, good nursing, sedatives, salicylates, pyramidon, arsenic or stramonium, but, unaffected thereby, the disease may run its usual course of six to 10 weeks or longer²³⁸^{243, 247}. Jones²⁴⁷ found streptococcal vaccine valueless. Small's antiserum (1927) helped only 13 per cent of Wetchler's²⁴³ patients.

Tonsillectomy Jones²⁴⁷ considered tonsillectomy indicated in cases of

choira with other rheumatic symptoms, but not particularly in "pure chorea." It should be done only when the disease is quiescent. Tonsillectomy has no effect on the course, duration or tendency to recurrences of chorea, but the tonsillectomized patient with chorea is much less likely to have endocarditis.²¹²

Nirvanol Results from nirvanol were satisfactory to Wetchler,²¹³ who had no complete failures in 115 cases. The disease was generally terminated within three weeks, although recurrences were not prevented. The plan of treatment and the "nirvanol reaction" were described and a brief review of the literature was given. Twenty-one moderately severe and five severe cases were treated by Bender and Pratt²¹⁶ with good results. Two patients had recurrences within a year. No harmful effects and no fatalities were encountered. Jones²¹⁷ used nirvanol in three cases, one patient had no febrile reaction and obtained no relief, another was unrelieved and a "very serious, almost fatal reaction with suppression of bone marrow" developed. Jones considered it a dangerous drug and its use unjustified.

Fever Therapy Some believe that the results with nirvanol and other fever-producing substances are due to the fever. Jones²¹⁷ used typhoid vaccine for fever therapy, his results (not fully reported) were not striking. The results of Sutton and Dodge (1933) with typhoid-vaccine fever reactions, however, were very striking, attacks were thereby shortened by an average of 36 days as compared with results when physical therapy, drugs, and diets were used. The average duration of attacks of 150 patients treated by vaccine reactions was 8.5 days, that of 150 patients treated otherwise 42.6 days. Sutton and Dodge^{220, 219} recently noted similarly good results with "artificial fever." Foreign protein shock is avoided, fever is controllable, and only one or two sessions (105° to 106° F. for five hours) instead of several daily reactions are necessary. Associated active carditis was not aggravated, indeed seemed to be benefited thereby.

Desjardins and Popp^{10, 72} considered artificial fever therapy most effective. All of nine children "improved satisfactorily." Daily fever sessions, at 103° to 104° F. for three to four hours, were given for one week. "In a week's time the attacks had passed." Two patients with chronic chorea treated by Hefke^{40, 51} were "improved," and of seven previously treated unsuccessfully with typhoid vaccine, six were controlled by artificial fever given by Schmidt.⁴⁵ Nine of 12 children treated by Schnable and Fetter⁷² were "cured" after an average of four fever sessions and had no recurrences within several months. Two children treated with low temperatures were only partially relieved. One child died 17 hours after collapsing during the first partial fever session as a result of a disturbance of the heat-regulating mechanism. In spite of this they regard fever therapy as offering the best chance of cure. (For comments on the general safety of fever therapy, the avoidance of unfavorable reactions and the probable inevitability of an occasional fatal reaction, the reader is referred to the discussion on fever therapy under "Treatment of gonorrheal arthritis"—Ed.)

CHRONIC ARTHRITIS

Incidence More statistics on the incidence and types of arthritis seen in general practice are needed. More available are statistics on the relative incidence of different types of arthritis seen in special clinics. Of 400 consecutive patients with "chronic arthritis" at the arthritis clinic of the Presbyterian Hospital, New York, 75 per cent had atrophic or hypertrophic arthritis³⁴. Of 200 consecutive patients with acute or chronic "rheumatic diseases" seen at The Mayo Clinic, 65 had atrophic arthritis, 39 hypertrophic arthritis, 30 had both types and 66 had other types of arthritis¹⁰⁶. Of Lang's²⁵⁰ 100 patients with chronic arthritis 47 per cent had atrophic, 21 per cent hypertrophic arthritis, 28 per cent had both types (and 4 per cent other types of arthritis?—Ed). Of Gray's²⁵¹ patients with chronic arthritis 70 per cent had atrophic, 30 per cent hypertrophic arthritis.

General Remarks on Etiology and Relationship of the Two Great Types There are four different opinions on the relationship between atrophic and hypertrophic arthritis: (1) that they are quite separate diseases of different etiology, the opinion of the majority^{11, 252}, (2) that the two types should be regarded as separate clinical entities, but may well have a common (but variable) etiology²⁵³, (3) that the two types are variants of one disease, caused by any one of a number of agents, and (4) that the two types are manifestations of one disease and have a single etiology. Thus both types were ascribed to "cold edema" by Bjorkman,²⁵⁴ to a sulphur deficiency, particularly of cartilages by Wheeldon²⁵⁵.

Distinctions Between the Two Great Types Clinical distinctions remain as previously reported^{1, 2}. Pathologic distinctions between the two types were again described by Parker and Keefer²⁵⁶ who insisted that the gross and histologic features of each are quite different even when both coexist in the same case. They therefore regarded as untenable the idea that both may result from the same underlying factors.

Roentgenographic alterations which appear as each type progresses were again reviewed by Doub¹¹ and by Ferguson, Kasabach and Taylor,²⁹ who analyzed 49 roentgenographic characteristics. Since varieties of bone atrophy, pitting and zones of erosion are common to the roentgenograms of many different types of arthritis (atrophic, hypertrophic, gouty, gonorrheal, tuberculous and others), it is agreed that there is no one pathognomonic feature in any one type. Each, however, has its characteristic picture or combination of alterations which may make the roentgenogram in a given case highly suggestive. These alterations, best seen in roentgenograms of hands, feet and knees, are as previously reported^{1, 2}.

(Roentgenographic features of each type have been described in numerous reports. Studies now much more to be desired are those on serial roentgenograms of the different arthritides—consecutive pictures taken of the same patients from the onset to the inactive stage of the disease. Such data, now very meager, are needed to determine the natural course of the disease and to establish the average and the minimal and maximal time that elapses between the disease's onset and the appearance

of each of the various roentgenographic abnormalities. Among the practical questions thus answered would be: How long must a roentgenogram of a painful joint remain "negative" before one can conclude that the disease in a given case is periarticular, not intra-articular, and probably represents periarticular fibrositis and not a mild slowly progressive atrophic arthritis?—Ed.)

Chemical differences between the two types of arthritis have been noted by several^{29, 31, 257-260} and are as follows. In atrophic arthritis the sedimentation rate is usually more than 30 mm. in one hour; agglutinins to hemolytic streptococci are usually present in high titer. There is an increase in plasma fibrinogen and globulin fraction, a fall in the albumin fraction, and the albumin-globulin ratio is frequently less than 1. Serum calcium is essentially normal and the plasma cholesterol tends to be decreased. In hypertrophic arthritis the sedimentation rate is rarely more than 20 to 30 mm., agglutinins to hemolytic streptococci and abnormal values for plasma fibrinogen, albumin and globulin are generally absent, the serum calcium is normal or slightly subnormal, and the plasma cholesterol tends to be elevated. These chemical differences lend support to the theory that the two types of arthritis are quite different diseases.

Constitutional differences have long been suspected, it being frequently stated that atrophic arthritis tends to appear in tall, thin, viscerototic persons, hypertrophic arthritis in short, stocky, obese, sthenic individuals. According to Pribram²⁶¹ who determined the biotype of the two, the brachymorphic group rarely develops atrophic arthritis but has a decided tendency to develop hypertrophic arthritis. Thus of 24 patients with atrophic arthritis, 15 were eumorphic (normal body build), 9 dolichomorphic (tall, thin, shallow-chested, underweight), none was brachymorphic (short, thick, overweight). Of 26 patients with hypertrophic arthritis, 8 were eumorphic, 16 were brachymorphic and 2 dolichomorphic. However, there are frequent exceptions to these generalizations. Dawson¹⁰³ frequently noted atrophic arthritis in the short, obese, pyknic type and hypertrophic arthritis in the tall thin type (though perhaps not quite as early as in the former).

ATROPHIC ARTHRITIS

Incidence. Atrophic arthritis is presumably much less common in the tropics than in temperate zones. However, new reports indicate that it is fairly common in Egypt (Abdel-Sayed)²⁶². In Australia it is more common in the southern (temperate) regions (Cooper¹⁶¹) than in the northern (tropical) states, in the latter it is less common than rheumatic fever.

Symptoms and Course. Howitt²⁶³ stressed the importance of recognizing the "rheumatic diathesis," and the prodromes of atrophic arthritis: loss of appetite and weight, tachycardia, a fall in blood pressure, slight fever, sweating hands and feet, tremors, general nervousness, extreme fatigability—"symptoms referable to overstimulation of the katabolic group of endocrine glands." Although atrophic arthritis may begin at any time of the year, its greatest seasonal incidence in Dawson's¹⁰³ cases in New York City

was in the spring, especially March. In more than 80 per cent of his cases the onset was between the ages of 20 and 50 years, the greatest incidence being at 35, the earliest onset at 14 months and the latest, at 78 years. Three females were affected to one male. Although the onset of the disease is usually insidious, and occasionally subacute, it was acute in 8 per cent of his cases, at first resembling rheumatic fever. In 100 consecutive typical cases mitral stenosis was found in 7 per cent.

Subcutaneous nodules are present in about 20 per cent of cases¹⁰³. According to Neligan²⁶¹ there are two types of nodules in atrophic arthritis: "millet seed nodules," described by Coates and present also in "rheumatic children without cardiac lesions" and larger nodules, often painful, which may be an inch or more in diameter and may persist for years. Neligan saw a 59 year old woman with atrophic arthritis who had over 100 nodules in different sites, varying in size "from an inch across to that of half a split-pea." They were intermittently painful, pressure sores had formed over some.

Atrophic Arthritis and Splenomegaly, Relation to Still's Disease and to "Felty's Syndrome" Adenopathy is common in atrophic arthritis, occurring in from 40 (Douthwaite, 1933) to 53 per cent of cases (Coates and Delicati, 1931). An enlarged or palpable spleen is present in from 10 to 15 per cent (Dawson¹⁰³) to 21 per cent of cases (Coates and Delicati). Atrophic arthritis, adenopathy, and splenomegaly in adults have been called by some "adult Still's disease," but the majority regard Still's disease of children or of adults as a variety of atrophic arthritis. Moncrieff¹⁰⁴ did not accept this view and regarded Still's disease and juvenile atrophic arthritis as different diseases. He considered unproved the idea of certain continental physicians that Still's disease is of tuberculous origin.

Chauffard (1896) and Still (1897) described the syndrome of arthritis, adenopathy and splenomegaly. Hepatomegaly was not mentioned by either, anemia was emphasized by Chauffard but not by Still. In Still's cases joints were enlarged but no changes in bone or cartilage occurred even in advanced cases, hence the distinction from juvenile or adult atrophic arthritis. In 1909 Herringham noted the association of arthritis, splenomegaly and hepatomegaly in adults. In 1924 Felty reported cases of chronic arthritis, splenomegaly, anemia and leukopenia, and debated whether they were cases of adult Still's disease, arthritis coincident with Banti's disease, or of a distinct clinical entity.

Fitz²⁶⁵ continued the discussion on relationships and described a case of "Still's disease" and one of "Felty's syndrome." In the former case deforming arthritis and splenomegaly were present but no adenopathy. No description of roentgenograms was given to indicate whether or not intra-articular disease was absent, as described by Still. The patient with "Felty's syndrome" presented deforming arthritis, hepatomegaly, splenomegaly, anemia and leukopenia, and died suddenly of an undetermined cause.

Castellani^{-66, -67} distinguished between "Still's disease" and "febrile hepato-splenomegaly of adults with arthritis," describing 3 cases of the latter, of men aged 45, 54 and 61 years. Features of the disease were slow onset of malaise, arthritic pains, a somewhat undulating irregularly-intermittent or remittent fever, and great enlargement and firmness of the liver and spleen. One or several large or small joints were swollen and painful. Adenopathy was absent. The blood picture varied: slight leukocytosis, slight leukopenia or a normal blood count were present at different times in the same cases. Various agglutinins were absent. The disease was progressive. In one case death occurred in 14 months. Because "in Still's disease there is no true hepato-splenomegaly, the spleen being palpable but not much enlarged, and the liver usually of normal size" Castellani did not regard his cases as being ones of Still's disease.

(Obviously various physicians define Still's disease differently. As we stated before,² it is interesting to note variations in the response of the reticulo-endothelial system in cases of arthritis, but a new name for each combination seems unjustified. Dawson¹⁰¹ thought there was no merit in the clinical segregation of "Felty's syndrome" or in the use of the term itself, which should be discarded. Until other evidence is available we favor considering these "syndromes" as varieties of atrophic arthritis.—Ed.)

Pathology. Pathologic changes in three cases of atrophic arthritis were described by Parker and Keefer.⁻⁵⁶ Primary changes were synovitis, characterized by an increase in the number of synovial cells, with thickening of the membrane, destruction of some synovial cells, and collections of lymphocytes, macrophages, plasma and rare giant cells. In some regions these collections were perivascular (as described by Fisher, 1929), in others they were not perivascular (as described by Allison and Ghormley, 1931). In the fat of periarticular tissue were perivascular lymphocytic infiltrations, in periarticular muscle there was degeneration and atrophy. Secondary changes were destruction of cartilage, atrophy of bone due to disuse and not to active destruction, subluxation, fibrous or bony ankylosis and muscular atrophy. Additional changes were lymphoid hyperplasia, calcification of blood vessels, amyloidosis, disturbances of growth and pigmentation of skin. Parker and Keefer do not agree with Nichols and Richardson (1909) or Allison and Ghormley on the mechanism of cartilage destruction. The latter stated that as the synovial pannus passes over cartilage, it adheres and destroys the cartilage, which is simultaneously being invaded and destroyed by connective tissue proliferation from subchondral spaces. Parker and Keefer believed that cartilage destruction is not necessarily from subchondral invasion, but from a solution of cartilage under the connective tissue pannus and from a "dedifferentiation" of cartilage into connective tissue.

(Much can be learned from pathologic specimens, from whatever source obtained. However, it is unfortunate that clinical histories in two of Parker and Keefer's three cases were not available. The errors and inadequacies of Nichols and Richardson's

otherwise admirable report resulted from a paucity of clinical data. Pathologic reports of cases fully studied from the clinical, chemical and roentgenologic standpoint are highly desirable—Ed.)

Laboratory Data Blood Counts and Hemoglobin Anemia is commonly present in atrophic arthritis, but it is evidenced by a reduction in hemoglobin content rather than in erythrocyte count. In 92 cases Collins²⁶⁸ noted only a minor reduction of erythrocytes, but the value for hemoglobin was normal (14 gm or more) in only 18 per cent. The value for hemoglobin was 13 to 14 gm in 26 per cent, 12 to 13 gm in 30 per cent, 11 to 12 gm in 13 per cent, 10 to 11 gm in 11 per cent and less than 10 gm in 2 per cent. This simple hypochromic anemia was much more frequent in females and bore no constant relationship to gastric anacidity. Severe anemia was seen in patients with normal gastric acidity. Gray, Bernhard and Gowen²⁶⁹ found anemia much oftener among clinic than private patients owing to the poorer living conditions and more advanced arthritis of the former. Hemoglobin was less than 80 per cent in 50 per cent of their private patients and in 81 per cent of their clinic patients. Erythrocytes were below four million in 14 per cent of private patients, in 39 per cent of clinic patients. As the disease progressed the value for hemoglobin dropped. In early cases a leukocytosis (over 10,000) and a shift to the left were more frequent. Steinberg²⁷⁰ found the Schilling hemogram shifted to the left in 78 per cent of 42 cases of atrophic arthritis, but in only 17 per cent of 17 cases of hypertrophic arthritis. Correlated abnormalities in both blood counts and sedimentation rates were generally found, but when disagreement was noted, Steinberg considered an abnormal Schilling count of more value than the sedimentation rate in differentiating the two types of arthritis.

Sedimentation Rates The value of this test in the differentiation and prognosis is reaffirmed by several.^{27 34, 196 271 269} Gray²⁵¹ noted the following. In early atrophic arthritis, rates were 0 to 10 mm (per hour) in 23 per cent, 10 to 20 mm in 37 per cent, more than 20 mm in 40 per cent. In "established arthritis" they were 0 to 10 mm in 14 per cent, 10 to 20 mm in 25 per cent, more than 20 mm in 61 per cent. In "advanced arthritis" they were 0 to 10 mm in 8 per cent, 10 to 20 mm in 25 per cent, more than 20 mm in 87 per cent. Rates were more than 20 mm in only 2 per cent of cases of hypertrophic arthritis. The rate of sedimentation is believed to depend largely on the concentration of plasma fibrinogen and globulin and on cell volume.

Blood Proteins To determine reasons for altered sedimentation rates Davis²⁹ studied blood proteins. The total proteins of blood were normal in both atrophic and hypertrophic arthritis but, in atrophic arthritis, there was an increase in plasma fibrinogen and globulin, particularly the euglobulin fraction, and a fall in the albumin fraction. The albumin-globulin ratio was frequently below one, but tended to become normal as the patient recovered. Since rises in plasma globulin often occur in infectious diseases, Davis con-

sidered this evidence that atrophic arthritis is an infection. These alterations in proteins were not seen by Davis in hypertrophic arthritis. The findings of Aldred-Brown and Munio²⁷⁷ were essentially similar except that they found in hypertrophic arthritis also a reduction of serum albumin, though not nearly so much as in atrophic arthritis.

Cholesterol The total plasma cholesterol tends to be decreased in atrophic arthritis (increased in hypertrophic arthritis, Hartung and Bruger²⁵⁹). The mean total cholesterol in 33 cases was 175.2 ± 39.5 mg per 100 c.c. of plasma. The cholesterol was normal (160 to 230 mg) in 49 per cent, below normal in 39 per cent and above normal in 12 per cent. The cholesterol partition (free ester) was normal. No correlation existed between sedimentation rates and cholesterol. Hypocholesteremia tends to support the infectious theory since other acute infections are accompanied by it.

Serum Calcium and Phosphorus Normal values were found in the 200 cases of Lahey and Haggart²⁷¹ and in all but one seen by Gray, Bernhard and Gowen²⁶⁹, one case had a low calcium-phosphorus index. Hartung and Greene²⁷⁸ found the values for the mean and standard deviation in 50 cases to be 10.218 ± 0.699 mg. calcium per 100 c.c., the same as in control cases. The serum calcium was slightly lower in hypertrophic arthritis. These findings do not quite agree with those of Race²⁶⁰ who noted a small but definite tendency to lower values in atrophic than in hypertrophic arthritis.

Magnesium Serum magnesium was essentially normal in both types of arthritis (Race²⁶⁰). Values were slightly lower in atrophic than in hypertrophic arthritis.

Blood Groups In 1000 cases of rheumatism (atrophic and hypertrophic arthritis, "subacute rheumatism," fibrositis) Race²⁶⁰ found the blood groups that would be expected from a random sampling of the general population.

Blood Pigments In cases of atrophic arthritis with a rapid sedimentation rate Race²⁶⁰ often found a marked diminution of plasma pigments. The icteric index was often as low as 3 units, sometimes even lower (normal about 6 units). Studies were in progress to determine whether the low plasma color was due to reduced lipochromes, bilirubin or both.

(These observations are of interest in connection with those of Hench (1933-34)⁴⁹ and of Sidel and Abrams (1934) that jaundice may induce a rapid and prolonged remission in cases of atrophic arthritis and of fibrositis—Ed.)

Urine Ellis (1927) and others suggested that there was an "alkaline diathesis" (deficient acid elimination) in atrophic arthritis, an "acid diathesis" (deficient alkali elimination) in hypertrophic arthritis. Race²⁶⁰ was unable to substantiate this contention. Urinary calcium was normal, and the pH, acidity, formol acidity and phosphate excretion were equal in both types.

Gastric Analysis Among 53 patients with atrophic arthritis Collins²⁸⁸ noted achlorhydria in 23, hypochlorhydria in five, normal acidity in 23 and

hyperchlorhydria in two. Reduction of acids bore no constant relation to anemia present. Hartung and Steinbrocker²⁷² noted achlorhydria in 27 per cent, hypochlorhydria in 17 per cent of 35 cases of atrophic arthritis, and achlorhydria in 26 per cent, hypochlorhydria in 3 per cent of 35 cases of hypertrophic arthritis. They considered that an abnormal frequency in the occurrence of subacidity is an important feature of chronic arthritis.

Electrocardiograms. The electrocardiograms in 50 cases of acute atrophic arthritis were found to be essentially normal by Master and Jaffe,¹⁹¹ in sharp contrast to those in cases of acute rheumatic fever.

Synovial Fluid. Normal synovial fluid probably contains about 200 cells per cu mm of which less than 10 per cent are polymorphonuclear cells, according to Collins.²⁷³ The total nucleated cell counts in 35 cases of atrophic arthritis were high (5,000 to 60,000 cells per cu mm). Counts in most cases were 10,000 to 20,000 cells. The percentage of polymorphonuclear cells varied from 40 to 90 per cent, in the great majority of cases being 70 to 90 per cent. These data agree essentially with those of Kcefer, Myers and Holmes (1934). The consistently elevated protein content of synovial fluid indicated the presence of an exudate, not a transudate. The ratio between blood and synovial sugar content was never significantly altered in atrophic arthritis. (In bacterially-infected fluids in specific infectious arthritis synovial sugar is usually markedly reduced—Ed.)

Etiology and Pathogenesis. The literature of 1935 repeated familiar arguments on etiology. Factors previously considered are again regarded as causal: the factor of infection, of trauma, of circulatory disturbance, of altered metabolism, of endocrine abnormality, and of neurogenic disturbances. Each factor is regarded by some as the essential one, the other factors being contributory.

Factor of Infection. Evidence for the theory of infection is direct and indirect. Direct evidence is presumably derived from cultures of blood, infected foci, lymph nodes, joint tissues and fluid, and from studies on the tropism and cataphoretic velocity of bacteria isolated therefrom.

1. *Blood cultures.* Gray^{251, 269} and his colleagues reported isolation of streptococci, mostly alpha (viridans) or alpha prime, from the blood in 48 per cent of 200 cases. Cases of early arthritis gave a much higher (65) percentage of positive cultures than those of established arthritis (positive in 36 per cent) or of advanced arthritis (positive in 26 per cent). Few positive blood cultures were obtained in summer. Cultures from infected foci often yielded the same types of streptococci. A small percentage of blood cultures yielded staphylococci and diphtheroids of undetermined significance. Control blood cultures were negative in all of 36 "normal" persons, and in all of 79 cases of hypertrophic arthritis, they were positive in 23 per cent of 22 cases of "acute focal infection," in 4 per cent of 26 cases of "chronic focal infection," and in 8 per cent of 89 cases of "arthralgia." (Were the latter cases of periarticular fibrositis?—Ed.)

Streptococci, generally "viridans," occasionally "hemolytic," were found

in 21 per cent of patients with atrophic arthritis, in 6 per cent of controls, by McEwen, Bunim and Alexander²⁹

2 *Other cultures* Although a variety of methods was used, cultures of synovial fluid were all negative in Collins' cases²⁷ Key³⁰ was unable to isolate streptococci from articular tissues, but found staphylococci in a third of joints studied. Streptococci of the alpha (viridans) or gamma (non-hemolytic) type were found by Gray and his colleagues^{31, 32} in 30 per cent of stools examined

3 *Electrophoretic velocity* Rosenow³³ again noted that streptococci, isolated in cases of atrophic arthritis and having a marked affinity for joints of animals following intracerebral injection, had a markedly "arthrotropic" cataphoretic velocity, usually 2.3 microns per second, volts per centimeter. Streptococci similarly isolated in cases of encephalitis had little or no affinity for joints but marked affinity for brains of animals and a markedly "neurotropic" cataphoretic velocity, usually 3.45 or 1.72 microns per second, volts per centimeter. The velocity of streptococci isolated from patients with "neuromyositis" was distributed between neurotropic and arthrotropic, about half of them having a neurotropic, the other half an arthrotropic potential. Previous similar work by Rosenow and Jensen (1930) was confirmed by Wood, Jensen and Post³⁴ who studied the cataphoretic velocity of streptococci (generally viridans, occasionally hemolytic rarely the "indifferent" type) isolated from 1173 cultures from foci in 215 cases of "focal infection diseases" including 90 cases of atrophic arthritis and 70 of neuritis. The method of cataphoresis was found useful in detecting reactions between antibodies and homologous bacteria. Given a stock suspension of bacteria with known pathogenicity and known mobility, specific antibodies in a patient's serum could be detected.

When Pratt, Sheard and Rosenow exposed them to short-wave radiation, arthrotropic streptococci lost their characteristic arthrotropic electrical potential and their affinity for joint tissues, and assumed the velocity of neurotropic bacteria and an affinity for brain. Conversely, neurotropic streptococci became arthrotropic and acquired affinity for joints. Changes thus induced were maintained in subcultures of these organisms^{27b, 27c}

(These experiments were done on bacteria in vitro. Do they suggest that exposure of an arthritic patient with arthrotropic streptococci to short wave therapy might change the invasive character of the patient's bacteria and his symptoms and make him "neuritic"? Rosenow's clinical colleagues treated a few arthritic patients with short wave therapy. Such clinical mutations, perhaps theoretically possible, have not been noted by them, or reported by others using short wave therapy.—Ed.)

4 *Indirect evidence* Indirect evidence supporting the infectious theory is derived from skin reactions to injections of certain bacteria, from the presence of agglutinins, precipitins, antifibrinolysins, and antistreptolysins, and from complement-fixation reactions

a *Skin tests* "Positive skin reactions" to one or more strains of

streptococci were found by Wainwright²⁷⁸ in 75 of 78 cases. A maximal reaction was to hemolytic streptococci in 88 per cent, to green streptococci in 8 per cent. Three cases showed no reactions. Skin reactions were absent in two and present in one case of Still's disease, absent in four and present in six cases of hypertrophic arthritis. Reactions diminished or disappeared when patients were treated with vaccines made from streptococci to which their skin was sensitive. Keefer²⁷⁹ and Dawson¹⁰³ have reminded us of the wide divergence in results obtained with such tests, and that their interpretation is difficult. All arthritic patients do not show positive reactions, some may react to organisms not found in their foci. In a given case a "positive skin test" does not in any way prove a causal relationship between the bacteria used and the patient's disease, although it may suggest that the patient is either infected with or is a carrier of the bacteria in question.

b Agglutinins Agglutinins to hemolytic streptococci, generally in high titer, were found in serums by Wainwright²⁷⁸ in 90 per cent of 87 cases, by McEwen, Bunim and Alexander²⁸⁰ in 88 per cent of 37 cases, by Blair and Hallman²⁰⁶ in 85 per cent of 62 cases. According to Dawson¹⁰³ significant agglutination occurs only with hemolytic streptococci, group A (Lancefield). Agglutinins for this group were usually definitely present in the cases of McEwen, Chasis, and Alexander²⁸⁰ but definite reactions were also obtained with other hemolytic streptococcal groups. Of Gray's²⁵¹ cases, 70 to 76 per cent had agglutinins (presumably to green streptococci, "alpha or alpha prime") in dilutions from 160 to 5120. Blair and Hallman²⁰⁶ found no correlation between agglutinin titers and the patient's age, duration of arthritis, number of joints involved or sedimentation rate. Others²⁰⁹ found it difficult to understand why titers increased in some and decreased in others who were progressing satisfactorily, and why titers increased one month and decreased the next. During the treatment of Wainwright's patients with streptococcal vaccine the agglutinins materially increased²⁷⁸.

The presence of such agglutinins is regarded by many^{103, 278, 279} as the strongest evidence in favor of the infectious theory of atrophic arthritis. They are found only rarely in patients with hypertrophic arthritis or in normal persons^{103, 206, 278}. Because, however, hemolytic streptococci can be isolated so rarely from affected joints, and because antifibrinolysins are *not* increased in atrophic arthritis (as they are in proved hemolytic streptococcal diseases and in rheumatic fever) one cannot finally conclude that the presence of streptococcal agglutinins indicates a causal relationship (Wainwright²⁷⁸). Keefer²⁷⁹ raised the question: Are these reactions a direct response to streptococcal infections, or are they indirect responses of a non-specific nature such as one sees in syphilis and typhus fever?

Formerly Rawls and Chapman²⁸¹ treated patients with vaccines made only from strains which patients' serums agglutinated, and inagglutinable strains were discarded as of no etiologic significance. Because some patients

so treated did not receive benefit, it was surmised that agglutination tests might not be reliable criteria for determining pathogenic specificity, since some causal strains might be inagglutinable (Freshly isolated strains of typhoid bacilli are sometimes inagglutinable—Ed.) Seeking more reliable tests of specificity, Rawls and Chapman²⁸¹ determined not only the agglutination tests, but the ability of strains of streptococci (isolated from infected foci of arthritic patients) to resist the "bactericidal" action of freshly-diluted defibrinated guinea-pig's blood in conjunction with their ability to produce arthritis in rabbits. Agglutinable strains killed by guinea-pig's blood produced arthritis in 88 per cent of injected rabbits, although large doses and multiple injections were required. Non-agglutinable strains killed by guinea-pig's blood produced arthritis in only 30 per cent of injected rabbits. Agglutinable strains not killed by guinea-pig's blood produced arthritis in 92 per cent of injected rabbits. The most pathogenic, however, were non-agglutinable strains not killed by guinea-pig's blood—these produced arthritis in 100 per cent of injected animals. Rawls and Chapman therefore concluded that certain inagglutinable strains were more pathogenic than agglutinable strains, particularly if they were also resistant to the bactericidal effect of guinea-pig's blood, and that agglutination tests in conjunction with tests of the resistance of a strain to the bactericidal action of guinea-pig's blood are of more value in assaying the specific pathogenic potentialities of any particular streptococcus than agglutination tests alone.

c Precipitins Precipitins for the C substance of hemolytic streptococci were found by McEwen and his colleagues²⁸⁰ in the blood of 80 per cent of 37 patients with atrophic arthritis, but they were also frequently found in other types of arthritis, even gonorrheal. In appraising their significance, therefore, caution must be exercised. There is a close approximation but not an absolute agreement between agglutination and precipitin reactions (Dawson¹⁰³).

d Antistreptolysins Antistreptolysins were increased (over 100 units per c.c.) in the blood of only a few of McEwen's²⁹ patients, and in the blood of only a third of Blair and Hallman's 45 patients²⁰⁶. In the latter cases high antistreptolysin titers with one exception accompanied high agglutinin titers. Of 32 miscellaneous serums tested for antistreptolysin, only seven gave high titers, two from cases of atrophic spondylitis, five from cases of chronic osteomyelitis.

e Antifibrinolysins Antifibrinolysins were not found by Myers, Keefer and Holmes²⁰⁸ in plasma in 11 cases and were only occasionally found by McEwen²⁹. Since antistreptolysins and antifibrinolysins are indexes of recent, acute, hemolytic streptococcal infection, perhaps one should not expect to find them in cases of chronic atrophic arthritis, although they are sometimes found in early acute cases.

f Complement-fixation tests These tests with streptococci were usually negative in cases of "acute or chronic polyarthritis" seen by Beck and

Coste⁻⁰⁷ They were usually positive to several streptococci, staphylococci and colon bacilli in the few cases of Gray et al⁻⁰⁹ who regarded the test subject to considerable error unless rigidly controlled. An occasional patient with atrophic arthritis gave an unexplained positive complement-fixation test to gonococci.

5 *Interpretation of evidence for the theory of infection* Investigators are discouraged in their attempts to discover direct indisputable evidence for this theory, hence their activity in searching for strong indirect evidence from various serologic and other reactions noted. An interpretation of these reactions is not now possible. Most of them are only relatively specific for atrophic arthritis, they are generally not specific for one bacterial strain and at best suggest, but do not prove, a causal association with streptococci. Indirect or circumstantial evidence is never as satisfying or convincing as direct evidence, nevertheless one cannot disregard it. One cannot deny the value of indirect evidence if it is found to be practically "specific." In the diagnosis of syphilis we have learned to rely heavily on the indirect evidence of an accurate serologic reaction, we no longer hunt for direct evidence—the *Spirochaeta pallida*. This analogy is worthy of further comment. The value of a positive Wassermann reaction lies in the fact that it is only "specific" to the extent that it is essentially pathognomonic of syphilis for the actual presence of spirochetes is not necessary for the reaction. Some by-product of the disease is responsible for the reaction. Hence it is possible that various streptococcal immune bodies in atrophic arthritis (and rheumatic fever) are by-products of the disease, responsible for reactions which may be proved to be more or less "specific" or pathognomonic of atrophic arthritis even though streptococci may not actually be the specific cause of the disease. Evidence for the theory of infection continues to be highly suggestive but is not yet conclusive.

The Theory of Bacterial Allergy Hypersensitiveness, not to one, but to several bacterial strains, proposed as a way out of this dilemma, is accepted by some,²⁸² but is meeting with increasing objections from others. Freeman's²²⁰ criticism of the theory was noted under the discussion on rheumatic fever. Keefer²⁷⁹ also regarded it as unproved. Although in many ways the hypothesis sounds attractive, Dawson¹⁰¹ concluded that "it is supported by singularly little evidence."

Virus Theory Coles²²² found "numerous virus bodies" in the synovial fluid in five of nine cases of atrophic arthritis. He regarded them of the same species as those he found in cases of rheumatic fever. No animal studies were made, hence no conclusions could be drawn.

Factor of Trauma That acute or chronic trauma from occupation, poor posture or recreation can predispose to, precipitate or aggravate atrophic arthritis is again emphasized by Hall¹³ and by Archer²⁸³. The latter believed that repeated trauma may produce atrophic as well as hypertrophic arthritis.

Factor of Circulatory Disturbance No new definite evidence is presented. Björkman²¹¹ regarded the local and systemic manifestations of atrophic or hypertrophic arthritis (as well as of fibrositis) as caused by local exudation from "cold edema."

(No proof is offered—Ed.)

Keefe²¹⁰ and Dawson¹⁰¹ cannot accept the idea that atrophic arthritis is caused by circulatory disturbances, because arthritis is not a complication of occlusive vascular disease and is infrequently associated with Raynaud's disease or scleroderma, because delayed removal of sugar from the blood of arthritic patients is variably present and also present in certain non-arthritics, and particularly because synovial membrane in atrophic arthritis reveals, not a decreased, but rather an increased blood supply, with many wide open capillaries.

(These pathologic findings link up with the bone atrophy present, for Jones and Roberts, 1934, found that bone becomes partly decalcified when its blood supply is increased, but becomes hypercalcified if its blood supply is decreased—Ed.)

Factor of Altered Metabolism Current theories are that there is a disturbance of sulphur metabolism, of liver function, or a vitamin deficiency, a food allergy, or an intestinal toxicosis. The origin of the idea that arthritis may result from abnormal sulphur metabolism has been reviewed by several^{215, 281-287}. The cystine content of certain tissues, such as finger nails, is considered a reliable guide to the sulphur metabolism of the body. The normal cystine content of nails ranges from 10.4 to 13 (average about 11.8) mg per 100 cc (Wheeldon,²¹⁵ Rawls, Gruskin and Ressa,²⁸¹ Argy,²⁸⁸ Sullivan and Hess, 1934). In "arthritic patients" the range is 6.5 to 13 mg (average variously reported at 8.2 to 9.8) (Sullivan and Hess, 1934, Argy,²⁸⁸ Woldenberg²⁸⁷). The range in Woldenberg's patients was 6.5 to 9.8 mg before, and 11.6 to 13 mg after, sulphur therapy. The cystine content of nails and the sedimentation rate of erythrocytes varied in inverse proportion²⁸⁸. Hess²⁸⁹ noted these concentrations in normal nails: cystine by the Sullivan method, 11.98 mg per 100 cc, and by the method of Vickey and Block, only 9.57 mg; arginine 6.6 per cent, histidine 0.46 per cent, and lysine 2.61 per cent. In the nails of patients with "arthritis" Hess found cystine, 9.78 per cent (Sullivan method), arginine, 6.62 per cent, histidine, 0.49 per cent, lysine, 2.63 per cent. Thus in nails of arthritics the three basic amino-acids were essentially normal, but the cystine was reduced. These workers made no attempt to subdivide "chronic arthritis." In atrophic arthritis Wheeldon²¹⁵ found the cystine content of nails was 7.9 to 10.6 (average 9.65) mg, after sulphur therapy the average rise was 1.63 mg. (In hypertrophic arthritis the content was 8.2 to 10.6, average 9.27 mg, after sulphur therapy the average rise was 2.35 mg.)

Because of these findings Wheeldon²¹⁵ suggested that "at least some, if not all, forms of arthritis are made possible by a sulphur deficiency, par-

ticularly in the cartilage of the joints, that, given a sufficient sulphur reserve to combat the contributing etiologic factor arthritis would not occur, and that, whether there is a sufficient sulphur reserve or not depends upon the ability of the intestinal tract normally to absorb sulphur."

Race⁶⁰ does not interpret the findings thus. The lowered cystine content of nails may be due, not to a disturbance of general sulphur metabolism, but to the reduced albumin-globulin ratio in blood plasma. The cystine content of globulin is lower than that of albumin, and the amount in nails may merely reflect alterations in plasma proteins. In a few cases of atrophic arthritis Race found a reduced blood glutathione, which probably resulted from the reduced number of erythrocytes as there is little or no glutathione in plasma. (Other evidence has been presented in favor of an abnormal sulphur metabolism. Goldthwaite (1904) noted loss of sulphur in atrophic, and sulphur retention in hypertrophic arthritis. Cawadinas (1925) reported a negative sulphur balance, indicating increased sulphur catabolism in "chronic rheumatics." Race (1927) denied the existence of a negative balance but noted increased urinary excretions of neutral sulphur in 20 of 42 patients with atrophic arthritis—Ed.) Senturia²⁵⁷ studied the sulphur excretion and partition in the daily urine of 18 patients with atrophic and 41 with hypertrophic arthritis. No appreciable deviations from those in 20 healthy persons were noted. His experiments tend to disprove the alleged existence of abnormal sulphur elimination or sulphur partition in the urine of arthritics.

Hepatic Dysfunction This is regarded by Todd²⁹⁰ as one of the basal factors in "chronic rheumatism." He noted the transient appearance of chronic muscular or articular rheumatism subsequent to catarrhal jaundice in certain cases. Tests for hepatic dysfunction were frequently more "positive" during periodic bouts of rheumatism than in subsequent remissions. (No details and no evidence thereof were given—Ed.)

Using the levulose tolerance test and considering a rise of 30 mg or more above the initial level in the blood during the test as evidence of hepatic inefficiency, Miller⁶¹ found some degree of hepatic impairment in about a third of all his rheumatic patients, in 31 per cent of 117 cases of atrophic arthritis, in 37 per cent of 41 cases of hypertrophic arthritis, in 36 per cent of 68 cases of fibrositis, in 28 per cent of 18 cases of sciatica, and in 33 per cent of 6 cases of gouty arthritis.

(He noted that Kimball (1932) found an abnormal levulose tolerance test in only one of 10 cases of chronic arthritis—Ed.)

Vitamin C Deficiency Subacute or chronic vitamin C deficiency produces in guinea-pigs an arthropathy which Rinehart²³³ believed was markedly similar to atrophic arthritis. Synovial proliferation, pannus formation, periarticular thickening, bone overgrowth and subcutaneous nodules are produced. Superimposed infection may accentuate the pathologic process. Rinehart was unable to produce arthritis with infection in the presence of adequate vitamin C nutrition. However, when vitamin C deficiency was first produced, areas of diminished resistance to subsequent infection re-

sulted. Infection plus vitamin C deficiency more readily produced scorbutic arthropathy in animals, lesions of which resembled those of atrophic arthritis. Many of the prodromal symptoms of atrophic arthritis are characteristic of latent scurvy. Some of his patients with atrophic arthritis presented evidence of vitamin C deficiency. Rimelhart therefore suggested that vitamin C deficiency may be a factor in the etiology of some cases called "atrophic arthritis."

Dietary Habits No direct relationship between dietary habits and chronic arthritis could be found by Hall and Myers,²⁹² who studied the dietary habits of 40 patients with atrophic and 27 with hypertrophic arthritis and 30 controls. No striking single abnormality in diet of any one group was found. Inadequate calories were consumed by 20 per cent of those with atrophic arthritis, by 37 per cent of controls. (Excess calories were taken by 59 per cent of those with hypertrophic arthritis, by 43 per cent of controls.) "Undesirable diets" were taken by 50 per cent of those with atrophic arthritis, by a third of those with hypertrophic arthritis, and by 40 per cent of controls. Some but not all arthritic patients took carbohydrates to excess and got inadequate vitamins and minerals, but so did some of those without arthritis.

Intestinal Toxicosis This condition causing arthritis may result according to Gutman²⁹³ from the improper metabolism of food as well as from infection in the "pathologic colon." However, Keefer²⁷⁹ found no constant deviation from normal gastrointestinal function in arthritis. Gastric anacidity, carbohydrate indigestion, and "abnormalities" in the colon are found inconsistently and no oftener than in other diseases, and there is no proof that they are significantly related to the course of the arthritis. Keefer found no gross or histologic evidence of atrophy or other disturbance in the intestines of four patients who died with atrophic arthritis.

Food Allergy Many persons are hypersensitive to certain foods and develop acute symptoms of various sorts. Some of these patients have a coincident atrophic arthritis. It has been suggested that the arthritis is related primarily or secondarily to the food allergy (Brown, G. I.²¹⁴), that the arthritis may be an allergic reaction to offending foods, or that an atrophic arthritis can be made worse by subsequent attacks of food hypersensitivity. No convincing evidence has ever been offered, new data are inconclusive. Among many patients Bauer²⁹¹ never saw one whose atrophic arthritis was traceable to food hypersensitivity.

Factor of Endocrine Abnormality Many physicians speak vaguely of endocrine abnormalities associated with or responsible for arthritis, but specific data are rarely given and definite evidence that such abnormalities occur in a significantly greater percentage of arthritics than in normals or persons with other chronic diseases is not at hand. Howitt,²⁹³ for example, considered the prodromal symptoms of atrophic arthritis "referable to

overstimulation of the katabolic group of endocrine glands, for atrophic arthritis is, like exophthalmic goiter and diabetes, a disease of the endocrine-sympathetic system" Todd²⁹⁰ stated that in chronic rheumatism, "subthyroidism is frequent. A pituitary factor is not infrequent. Ovarian dysfunction with oligomenorrhea or amenorrhea is common in atrophic arthritis." Another²⁹¹ contributed this gem: "Experience points to a close connection between arthropathies and endocrine glands. Constitutionally the dolichomorphic type, probably governed by the anterior pituitary, thymus and interstitial gonads and influenced by the thyroid and adrenal glands is associated with atrophic arthritis, while the brachymorphic constitution, dominated apparently by thyroid, Langehansian body and gonads, seems most frequently connected with the hypertrophic type" (There we are, its as clear as that! But to make it easier certain endocrines were recommended "whenever the condition demands opotherapy"—Ed.)

1 Alterations in thyroid function. Some consider hypothyroidism, others hyperthyroidism, causally related to arthritis and report significant deviations from the normal metabolic rate fairly frequently in arthritics. Hall and Monroe (1933) found rates below — 10 in 36 per cent of cases, and below — 17 in 18 per cent. However, Monroe²⁹⁰ reported that the incidence of atrophic arthritis in 98 cases of myxedema and in 414 cases of hyperthyroidism was low, probably no more than would be expected statistically. Of the hyperthyroid patients, 3 per cent had atrophic arthritis, 2 per cent had hypertrophic arthritis, 4 per cent had arthralgia or myalgia, 1 per cent had bursitis, and 90 per cent had no joint disease. Of the myxedematous patients, 3 per cent had atrophic arthritis, 5 per cent had arthralgia and myalgia, none had bursitis, 60 per cent had no rheumatism, but 33 per cent had hypertrophic arthritis. This may have been due to the fact that the average age (51 years) of the myxedematous patients was 15 years greater than that of the hyperthyroid group, an age when hypertrophic arthritis makes its almost universal appearance.

Duncan (1932) stated that patients with preexistent atrophic arthritis showed exacerbations of symptoms when hyperthyroidism developed, that joint pains were often associated with hyperthyroidism, and that thyroidectomy afforded marked, prompt relief to joints. Bach²⁹⁷ reported three such cases. One case was detailed that of a young woman with polyarthritis and "slight but definite signs of hyperthyroidism" which later became marked. After thyroidectomy "immediately the pains, stiffness and periarticular swelling disappeared" without recurrence.

(It is the belief of the majority of the editors that the relief experienced in some cases from thyroidectomy, parathyroidectomy and so forth is quite nonspecific, the result not of *the* operation, but of *an* operation, and that almost any surgical operation may produce similar results. Such dramatic relief is often seen in the upper extremities after lumbar sympathectomy, it is also seen after appendectomy, cholecystectomy, tonsillectomy, and splenectomy. Unfortunately the relief is usually transient, merely a brief remission having been induced. Occasionally, however,

relief is prolonged. In evaluating the effect of any surgical procedure in arthritis one must [but most writers do not] take this nonspecific postoperative effect into account. However, one of us, A. A. F., believes that the correction of hyperthyroidism may exert some "specific" influence on the course of the disease—Ed.)

Metabolic rates were determined by Gray, Bernhard, and Gowen²⁶⁹ in 47 cases of atrophic arthritis, 53 per cent gave minus readings (average -7), 47 per cent gave plus readings (average $+14$). The rate tended to drop as the disease progressed, the average rate in cases of advanced arthritis was -9 . In two cases hyperthyroidism developed, the effect of thyroidectomy thereon was not noted.

(These figures do not tell us much. It is not stated how many cases had definitely abnormal rates—over 15 or under 15 per cent—Ed.)

Race²⁶⁰ and Dawson¹⁰³ concluded that patients with atrophic arthritis show no significant deviation from rates seen in a group of normal or chronically ill persons.

2. Parathyroid dysfunction has recently been advanced as the cause of certain cases of arthritis, including the atrophic type, and particularly of ankylosing spondylitis. Parathyroidectomy is being performed²⁶⁸. The subject will be discussed later under "Relationship between arthritis and hyperparathyroidism". Suffice it to say here that Lahey and Haggart²⁷¹ found in 200 cases of atrophic arthritis no clinical, chemical or roentgenographic evidence of hyperparathyroidism.

Factor of disturbance of the sympathetic nervous system. Although several of the year's writers glibly spoke of atrophic arthritis resulting from disturbances of the sympathetic nervous system, no new data to support the idea are at hand. Disturbances of the sympathetic system have been considered responsible for the vasomotor symptoms of the disease. These symptoms can be largely cured by sympathectomy, but opinions differ as to whether the arthritis is also cured thereby. Keefer²⁷⁰ stated that before one can blame arthritis on these vasomotor symptoms it must be shown that (1) all patients have these changes prior to their arthritis, (2) vasomotor reactions are capable of producing inflammatory changes in synovia, (3) the arthritis can be arrested by sympathectomy. It was his opinion that vasomotor disturbances undoubtedly contribute to the symptomatology of atrophic arthritis, but that neither they nor other functional alterations in the sympathetic nervous system have been proved responsible for the disease, or their sole correction entirely responsible for a cure.

Relation of Atrophic Arthritis to Rheumatic Fever. This was discussed under the section on rheumatic fever.

Relation of Atrophic Arthritis to Tuberculosis. Some believe that many, if not all, cases of atrophic arthritis represent "tuberculous rheumatism," an atypical, possibly allergic, reaction induced by tubercle bacilli (Copeman¹⁰⁰). The idea was discussed under "Tuberculous rheumatism". Forestier⁴¹ spoke of an attenuated form of tuberculous arthritis of the

fibrous type, a transition type between true atrophic arthritis and what the French call "tumeur blanche". Tuberculosis was rare among Dawson's¹⁰⁷ 800 patients with atrophic arthritis, only three having it. Moncrieff¹⁰¹ accepted the evidence that positive tuberculin reactions in arthritic children are no more numerous than one would find in a group of healthy children of the same ages.

Conclusion on Etiology No extended comment is necessary. Obviously the cause of atrophic arthritis is unknown. At present the infectious theory remains dominant (and we feel rightly so), but it is far from proved.

Treatment—General Remarks Arthritis is one of the two diseases most poorly treated by physicians, according to Yater²⁹⁹ who, however, found excuses therefor. Chronic arthritis requires months or years of consistent treatment, which is difficult when most patients change physicians so often. Markedly disabled, the patient may be unable to earn money for proper treatment. Little is known regarding the cause or cure of the disease, and, as to what is the best treatment, there is much confusion in the minds of general practitioners. (In the minds of some "rheumatism specialists" also, may we add—Ed.)

Those of wide experience agree that since no "specific" for the disease is at hand, the patient and not just his disease must be treated, perhaps the patient even more than the disease. A broad approach to the problem of treatment is required, and regardless of individual opinions on the relative importance of this or that causal factor, whatever physiologic abnormality a patient presents, whatever coincident or related infection, endocrine or metabolic disturbance, or postural or occupational strain, is present should be corrected as far as possible in order to help the patient cure himself of a disease which the physician can't, or hasn't yet learned how to, cure.

This necessitates a "combined attack," but the attack is intended to overwhelm the disease, not the patient, and the latter must not be swamped by a too energetic or too inclusive treatment. The plan of treatment must therefore be individualized to suit the requirements of each patient at the moment. The program of therapy should have latitude and longitude. First will be used, not every accepted form of treatment, but only a selection of those measures which the stage of the disease, and the patient's physiologic make-up, constitution, and finances, warrant. In the first few weeks of a rather healthy patient's mild disease one perhaps could not well defend treatment by radical removal of foci to the extent of removing, for example, a questionably-infected gall-bladder or a hyperemic cervix. A little later, however (but not too late), when the arthritis appears formidable such measures may be defensible.

In the presence of a poor patient with an obviously subsiding chronic arthritis one could hardly defend the institution of a long and expensive course of even the most touted vaccine. In some regards nature is a poor rheumatism specialist, particularly when she fosters flexion deformities and ankyloses. But nature may be a good physician if given a chance and

helped, not hindered, especially early in the disease, when the patient is so apt to traumatize his diseased joints and to deplete his strength by sleepless nights and anxious days. When it is apparent that a benign nature has things under control, it is perhaps best for the physician to be an admiring spectator and not a too obtrusive fellow-actor. If physiologic equilibrium is being satisfactorily obtained without vaccines, it is best to hold their use in abeyance, since we know too little about the mechanisms involved and may do harm, not good. If, however, one is faced with a relentlessly progressive disease, it seems folly to withhold vaccines "because they only help one in three or four." That fourth patient deserves his chance for relief. At times, therefore, the combined use of several measures may be necessary, and the program may quite justifiably include certain fairly safe remedies which are not yet "standard."

The program of treatment must also have longitude. It must be planned so that it can be kept up over a long period of time as efficiently, and yet as inexpensively, as possible. This means substitution of at least part of professional physiotherapy by home physiotherapy, the use of the less expensive (but just as good) analgesics by mouth rather than fancy-named salicylates or other medicines by vein. The physician must foresee the probable necessity of modifying treatments to meet changing circumstances. He should be planning what to do next if in a particular case the current program fails after a reasonably, but not unreasonably, long trial period. The patient should know that the physician does have a second, third or even fourth line of defense, that other measures with a reasonable likelihood of success are available as necessary. This creates the confidence and optimism so vital to the arthritic patient. Although the physician may alter details of treatment from time to time, he will constantly impress upon the patient the importance of continuing those fundamental principles of treatment which apply to all chronic, especially infectious, diseases—the necessity of extra periods of rest, adequate diet and so on.

The array of measures suggested hereafter shows only too well that no one remedy is consistently helpful. Each must be regarded as part of a mosaic, not to be used alone or judged too much on its own merits. Herein, however, lies the difficulty in evaluating researches on treatment, for in most cases the measure used was but part of a larger plan of treatment, though the writer often fails to mention the fact. *Thus the matter of setting up controls is so difficult, yet so important.*

Infected Foci and Their Management The controversy as to relationship between infected foci and chronic arthritis is still actively discussed^{279, 282-300}. Pemberton²⁵³ again stated that many infected foci are the result, not the cause, of the disease. Of 300 patients with "chronic arthritis," 66 per cent of those with atrophic and 47 per cent of those with hypertrophic arthritis had had infected foci removed before he saw them. Nevertheless he found infected foci in 79 per cent of those with atrophic and in 81 per cent of those with hypertrophic arthritis. Obviously the pre-

vious removal of infected foci had either been done incompletely, or other foci had subsequently developed. Obviously, also, many were not helped by removal of such foci. However, others believe that results obtained from the removal of foci leave little doubt as to the value of this procedure, which in their opinion is the *sine qua non* of therapy^{300, 301}. Removal of foci alone is rarely successful, and when it is to be done in the case of depleted malnourished patients, the patient should be "built-up" beforehand³⁰². One should distinguish according to Sherwood³⁰³ between unwall-off infected foci which may produce systemic disease, and walled-off infections such as dental-root cysts, which he considers harmless.

If removal of a focus is followed by either exacerbation or disappearance of the arthritis, a relation between focus and joints is generally assumed. However, improvement following removal of foci may be due to a general "stimulation resulting from removal of one cause of a lowered resistance"^{279, 282}. When neither improvement nor exacerbation occurs it is assumed that the removed focus was not the cause, or that the arthritis was too established for focal removal to help. Stated reasons for doubting the theory of focal infection include failure of improvement in arthritis after removal of foci, cases of arthritis without demonstrable foci, improvement of arthritis without removal of foci, frequency of infected foci in non-arthritics, and inability to obtain consistently the same bacteria from foci and joints.

1 Teeth. Some favor the removal of dead teeth,²⁸² others consider them harmless and remove only definitely infected teeth^{34, 103, 300}. If many are to be removed, some remove four or five at a time, with intervals of two weeks between sessions.

2 Tonsils. Of 500 patients with "arthritis" seen by Nissen,³⁰⁴ 10 per cent had had their tonsils removed prior to the onset of the disease. 90 per cent had not. The course of the arthritis in these two groups was studied. Infected tonsils should be removed only during a period of relative arthritic quiescence. If such a period does not appear, or if in a given case the arthritis is constantly progressive, Nissen believed "tonsillectomy is never indicated". (He considers "arthritis" of many types all one disease. The types are not differentiated, hence no conclusions can be drawn—Ed.)

3 Infected sinuses. Infected sinuses including "silent sinusitis" are rarely a focus in arthritis according to some, not uncommon according to others^{103, 300}. Conservative treatment should be thoroughly tried before operation²⁸².

4 Nasopharyngitis of the diffuse type, even in the absence of tonsils may act as a focus (Willcox³⁰⁰).

5 Gall-bladder. That an infected gall-bladder may be the sole causative focus in arthritis, Patterson³⁰⁵ concluded from observations on one patient who noted prompt relief on two occasions once after an appendectomy and (presumably) a cholecystostomy (with subsequent relief for eight years), and again after cholecystectomy. Nonhemolytic streptococci

were found in the gall-bladder, a vaccine of which produced joint symptoms (Although prolonged remissions were obtained after both operations it is still possible that relief was due to a non-specific postoperative effect—Ed)

6 Uterine cervix, and prostate gland Infection of these is in most cases responsible, according to Robinson³⁰⁶ for arthritis He noted consistent improvement only when these (and not other infected foci) were treated "There is no remedy for it except (long-wave) diathermy given intrapelvically by special electrodes"

7 Secondary colon infections These according to some^{293, 300} are frequent, according to others rare³⁰⁷ Their importance is often exaggerated

Bacterial Vaccines, Antigens, Filtrates Of those writers who have recently expressed an opinion on vaccines, about 60 per cent have favored their use, 40 per cent have not Milliken³⁰⁸ gave to 25 patients with "chronic arthritis" a mixed vaccine (streptococci from blood, tonsils and colon added to Clawson and Wetherby's vaccine) An average of 36 injections was given over an average period of four months Systemic reactions were avoided, small doses used Patients were treated until they remained symptom-free for at least 30 days "Complete relief" was obtained by 12 patients (48 per cent), the average duration of their disease was 30 months "Moderate relief" was obtained by eight patients the duration of whose arthritis averaged 69 months Five patients (20 per cent) who had had the disease on an average of 106 months received little or no relief The best results were obtained in early cases and by those with the greatest tolerance for the vaccine (No other treatment was mentioned The series is very small, no controls were used, and the "arthritis" was undifferentiated—Ed)

Intravenous injections of streptococcal vaccine from strains to which patients were "skin-sensitive" were given by Wainwright²⁷⁸ to 45 patients, 30 (66 per cent) were "improved" Desensitization was attempted by using very small doses Constitutional reactions were avoided, but focal reactions in joints were common Improvement was slow but generally progressive and was first noted in four to six weeks Agglutinins increased, and skin-sensitivity diminished or disappeared The sedimentation rate was variably affected in those who improved steadily dropping in some, and remaining elevated in others despite definite objective and subjective improvement Hence Wainwright considered it of doubtful value as a test of improvement

Sherwood^{303, 309} reported further experiences with vaccines An earlier series consisted of 674 cases of "arthritis" ("atrophic or periarticular" 311 cases, "rheumatoid" 32 cases, hypertrophic arthritis 260 cases, gonorrheal 19 cases, and a few cases of neuritis and myalgia) About 60 to 70 per cent of patients in each group were "markedly improved" Treatment of four different types was "almost wholly with vaccines" Clawson and Wetherby's (Lilly Streptococcal Vaccine), Cutter's mixed respiratory vac-

cine, and two modifications of the latter. Results with each vaccine were about the same (Sherwood's "rheumatoid" cases were apparently those of early atrophic arthritis "with no bony change." No comparisons were made with patients treated by other methods than the use of vaccines—Ed.) Sherwood later treated 300 "arthritic" patients, of whom 100 each were treated with "Cutter's arthritis vaccine," with a casein solution, and with physiologic saline solution. Patients were assigned the solutions in rotation, the contents being unknown to the administrator. Within eight weeks (a very early time—Ed.) "marked improvement" was noted by two-thirds of those treated with vaccine, by half of those with casein, and by a third of those with saline; relief by the last-named measure was regarded as from mild psychotherapy.

Streptococcal vaccines were approved by several^{250, 251, 274, 307, 310}. Gray²⁵¹ found low complement in patients reacting unfavorably to minute doses. Various vaccines and antigens were given intravenously and subcutaneously by Boots,³⁴ Dawson,¹⁰³ Holbrook and Hill³⁰² without striking differences in results with different vaccines or in controls. They concluded that vaccines are of unproved value, generally harmless, have a psychotherapeutic value, and serve to bring the patient to the physician's office for more important therapy and control. Results vary with the enthusiasm of the user. Kinsella's³³ results were "unimpressive." Of 21 European physicians who had used "specific vaccines" Slocumb³⁰ found only nine who were continuing them. Yater²⁹⁹ thought that general practitioners should not be encouraged to use vaccines for arthritis lest they neglect more valuable methods.

Long-continued vaccine therapy was considered by Reiman and Eklund³¹¹ to be the cause of amyloidosis in the case of a young arthritic who died of uremia after having received 41 injections of vaccine in 22 months. His blood protein was 4.71 gm, albumin 0.74 gm, globulin 2.67 gm per cent, fibrinogen 1.29 gm per 100 cc.

(Parker and Keefer²³⁶ noted amyloidosis as part of the secondary pathology of the disease. Therefore, the disease and not the vaccine may have caused amyloidosis—Ed.)

The failure of autogenous vaccines to help more than 48 per cent of their patients led Lamb, Anderson, and Nerb³¹² to use filtrates (antivirus) of autogenous streptococci to which patients were "skin-sensitive." Of 70 patients with atrophic arthritis, 13 per cent "recovered," 36 per cent "greatly improved," 36 per cent improved slightly, 15 per cent were unimproved.

(No controls treated without vaccine or filtrates were studied—Ed.)

Intravenous doses of urinary proteose from arthritic patients gave no encouraging results (Kinsella³³).

Foreign Proteins. The actions and uses of, and contraindications to foreign protein therapy were reviewed by Hektoen³¹³ and Cecil²³⁴ who

regarded this treatment in selected cases as distinctly useful even if not brilliant. It generally does no harm although it may do no good. Cecil believed that foreign proteins should always be tried in acute arthritis unrelieved otherwise. Many of his early patients with atrophic arthritis "remained well" thereafter, many with chronic arthritis were definitely improved. Other authors^{34, 103} considered it of doubtful value.

Diet Pemberton²⁵³ again stressed the value of a diet adequate in proteins, vitamins, and calories, but with a reduction of concentrated carbohydrates. "There is some evidence to suggest that in selected cases a difference of 300 calories might turn the scale in favor of retrogression or improvement." He and Scull^{314, 315} considered that the value of their diet was explained by the fact that one of the dynamic pathologic changes in atrophic arthritis is a disturbance of water distribution in tissue, exemplified by the common appearance of edema in periarticular tissues. Their diet tended to provoke a negative water balance, which reduces swelling and inflammation.

(These water-balance studies were calculated only semi-quantitatively. The total acid-base balance and the insensible perspiration were not fully determined.—Ed.)

Considering the edema of arthritis as due to a low plasma albumin, Davis²⁹ regarded protein restrictions as harmful. A generous intake of protein may lessen the edema.

To correct supposed hepatic dysfunction in atrophic arthritis Todd²⁰⁰ "spares" the liver by prohibiting all fats (except butter and oils) and lactalbumin. (No acceptable proof of the need or value of this diet was given.—Ed.)

A diet high in "protective foods" (fresh fruits and vegetables), but moderately low in proteins and calories and low in carbohydrate, was used by Langstroth³¹⁶. Others thought that a low-carbohydrate or low-protein diet did more harm than good (Boots³⁴). Lookie²⁹ found restriction of carbohydrate of no merit and excesses of carbohydrate apparently not harmful, several patients continued to improve despite a daily intake of 500 gm for 15 to 65 weeks. The administration by Hensch²⁹ of 400 to 600 gm of carbohydrate daily for many weeks to patients whose atrophic arthritis was temporarily inactivated by jaundice did not counteract the analgesia with jaundice nor bring out symptoms of arthritis. Studies by others (Bauer,²⁰⁴ Hall and Myers²⁹²) did not indicate any abnormality in carbohydrate utilization or suggest that excess carbohydrate intake was an important factor. They saw no theoretical or clinical value in a low-carbohydrate diet.

(Our opinion is divided on this point. The majority agree with the foregoing views. Others believe that disturbed nutrition forms the background of much ill health from infection and that almost all nutritional deficiency states are best controlled by carbohydrate restrictions. Hence, they favor the view that nutritional disturbances are a causative factor in atrophic arthritis.—Ed.)

The majority favor no particular dietary restrictions, prescribe a generous intake of food except when reduction of the trauma due to obesity is

required, and believe that most patients do badly on prolonged dieting or starvation^{29, 34, 106, 291, 294, 301, 302, 310}

Excess feeding of vitamin C was advocated by Rinchart²³¹, improvement in capillary resistance tests (an index of latent scurvy) and in joints was noted. However, such feedings by Faulkner²²⁰ for four weeks were not helpful. Some believed vitamin deficiency played no rôle in the disease^{292, 294}. The results obtained by Bauer's patients²⁹ who adhered to a high-vitamin diet for three to five years were no better than those seen in his patients who had not been so treated.

For weak patients, a high-calorie diet and insulin just before meals are prescribed for a month by Copeman³⁰¹ (15 units once daily) and by Eaton³¹⁷ (5 to 20 units three times a day).

Additional Intestinal Therapy Colonic irrigations are still recommended by some, and condemned by others^{34, 252, 293, 299, 318}. The reported abnormalities in intestinal configuration were not found in 50 cases by Lang²⁵⁰. There is no evidence that these "abnormalities" (if they really are abnormalities) are related to atrophic arthritis. Possibly they result from (any) chronic illness^{279, 294}. Wyatt³⁰⁷ found no consistent evidence of faulty elimination. Cathartics can be replaced by exercise, regular habits, diet, and simple lubricants.

Iron, Blood Transfusion Only two of 21 anemic patients of Collins²⁶⁸ responded well to massive doses of iron. Transfusions may improve those with acute or subacute arthritis, with or without anemia, but are of little value in chronic afebrile cases^{251, 301, 302, 307}. Intragluteal injections of leukocyte extract improved Hartung's patients²⁹.

Miscellaneous Substances Cinchophen derivatives are very useful drugs which have been condemned unjustly, according to Snyder²⁹ and Eaton³¹⁷ who noted no significant toxicity therefrom. In the present state of our knowledge no endocrine therapy is specifically indicated¹⁰³. Nadler³¹⁹ warned against the use of dimithiophenol in arthritis, peripheral neuritis and multiple joint pains may result.

Gold Salts Gold salts are given in various preparations, solganol (aurothio-glucose), allochrysin (sodium aurothiopropionol sulphate), myoral, sanochrysin, myochrysin (gold sodium thiomalate), gold thioglycolate, or gold sodium thiosulphate (crisalbine). Some are given intravenously, others intramuscularly in aqueous solution or oil suspension. Colloidal gold, gold chloride or gold cyanide are ineffective (Forestier⁴¹). Contraindications to gold are the presence of severe diabetes, nephritis, hepatitis, marked hypertension or hemorrhagic tendencies. Doses are usually given weekly until a total of 15 to 2 gm is given. Some give only one course, but Forestier stated "no case of rheumatoid arthritis has ever been cured by a single series of injections." According to him at least two courses are always necessary, with an interval of not more than six to eight weeks between.

Many patients are sensitive to gold and reactions are common. Focal

reactions include increased joint pain and swelling. Mild general reactions include fever, urticaria, pruritus, "gold bronchitis or flu," herpes. They may not necessitate cessation of treatment. Severe and occasionally fatal reactions may occur as skin and mucosa, liver, kidneys and blood cells are affected. Symptoms are erythematous rashes, occasionally exfoliative dermatitis, albuminuria, hematuria, or acute nephritis with uremia, stomatitis, jaundice and severe hepatitis, iritis, vomiting, hiccough, and diarrhea (Abdel-Sayed,²⁶² Foestier,⁴¹ Hartfall and Garland,³²⁰ Holmes,³²¹ Slocumb,⁹⁹ and Slot⁴²). Agranulocytosis and fatal hemorrhages have been noted (Poynton²²⁰). One patient was delirious for two weeks (Abdel-Sayed²⁶²). Holmes³²¹ heard of two fatalities and had one patient recover from severe dermatitis. Of 100 patients treated by Hartfall and Garland three died of exfoliative dermatitis. Sixteen of 21 "rheumatic" patients treated with gold developed, after one or two injections, punctate basophilia and polychromatic blood cells which sometimes persisted 10 months.³²² In spite of these marked and even fatal reactions, however, some frankly considered gold the most effective treatment of the disease.^{41, 12, 320} Gold must be given carefully to selected patients by physicians alive to its dangers. Of Abdel-Sayed's²⁶² 14 patients, six were "cured," five improved. Of 100 patients of Hartfall and Garland's³²⁰ 70 per cent were "apparently cured or markedly improved." Pemberton³²³ (Liverpool) treated 69 patients 18 per cent were cured, 40 per cent much improved, 32 per cent improved. Foestier⁴¹ treated 550 patients, "between 70 and 80 per cent responded favorably." Fifty per cent of patients with early arthritis and 20 to 30 per cent of those with old arthritis were "apparently cured" by two to five series of injections, and they remained so for two or three years without other treatment.

(None of the editors has used this method. Untoward reactions have appeared often enough to make one very conservative regarding it. No other current non-surgical treatment for arthritis (including fever therapy) has a mortality of 3 per cent, which is that of one series. Results would have to be unquestionably superior to warrant this risk. No control series were reported by most of the writers. Many patients had supplementary treatment which was frankly discounted—Ed.)

Sulphur It is claimed that injections of colloidal sulphur elevate the cystine content of nails to normal, reduce the sedimentation rate, and improve the joints in the majority of cases. Sulphur is injected intramuscularly, intravenously, or both. Rawls, Giuskin and Ressa²⁸⁴ treated 200 patients with "arthritis." Some who did not respond to small doses (10 mg twice weekly) obtained results from 20 to 30 mg twice weekly. A few showed evidence of an overdosage after intravenous but not after intramuscular injections, the symptoms being fatigue, headache, drowsiness, anorexia, and increased joint pain. Greater toxicity temporarily developed in a few cases: urticaria and erythema, nausea, vomiting, cramps, diarrhea, and chills and fever, however, these soon disappeared. Of 33 patients with

atrophic arthritis, 15 were "improved" Those with a low cystine content of the nails received the most benefit Some were previously given a placebo (Ringer's solution intravenously) for six to eight weeks, improvement with sulphur was greater

Wheeldon²⁵⁵ treated 892 patients with "chronic arthritis" with sulphur He reported results in 25 cases each of atrophic and hypertrophic arthritis resistant to other therapy Each patient received 40 intravenous and 40 intramuscular injections of "Sulfur-Diasporal" "Every case improved subjectively" Muscle spasm was reduced in 85 per cent, and joints became smaller in 65 per cent, many becoming more movable Detailed studies were made on the physiologic effect of sulphur on the cystine content of nails, sedimentation rate, blood count, sugar and calcium, urinary indican, blood pressure and weight

Woldenberg^{285, 286} treated 231 patients with atrophic arthritis "Every case showed excellent clinical improvement" Best results were from 30 mg of colloidal sulphur (Sulfur-Diasporal) intravenously daily for 10 days "In the majority of cases patients were free from pain after five or six injections" Sometimes in acute cases a dose of 30 mg intravenously "completely rid the patients of the intense pain they were suffering within 36 hours of the first injection" "So far as we know no recurrences of the disease have taken place" (It is difficult indeed to believe these extravagant statements, particularly in view of the more conservative reports of others The patients also received physiotherapy daily No control series was observed and no details of the follow-up are given—Ed)

Of 11 patients who were given an average of 60 cc (600 mg) of colloidal sulphur (sulisocol) intravenously by Sashin and Spanboch,³²⁴ six "improved," five did not No conclusions were drawn McCarty³²⁵ found sulphur "helpful in a small series of cases" Todd²⁹⁰ approved such therapy However, Kinsella³³ noted no definite improvement in 50 to 60 patients, and in 12 cases of Dawson¹⁰³ it was "absolutely without effect"

Choline and Histamine These substances are being applied by iontophoresis to produce pronounced local and mild general vasodilation without the unpleasant systemic reactions from their parenteral use After iontophoresis with mecholyl (acetyl beta methylcholine chloride) such an effect lasted six to 10 hours, according to Abel³²⁶ who treated 11 patients with atrophic arthritis, 10 were "definitely improved" Two patients with Strumpell-Marie's disease were not benefited Kovacs³²⁷ regarded mecholyl iontophoresis the method of choice in the local treatment of small joints in cases of atrophic arthritis During iontophoresis the drug is actually absorbed, resultant physiologic effects on dogs were demonstrated by Kotkis and his associates³²⁸

Producing less vasodilation, mecholyl is inferior to histamine, according to Kling¹⁷ who tabulated reported results of histamine iontophoresis for "rheumatic affections" of 730 patients 84 per cent were "cured or improved" Kling treated 12 patients with "spondylarthritis and radiculitis",

seven improved Of eight patients with "sacroiliac arthritis" two improved, of eight with atrophic arthritis seven improved after 10 to 20 applications Treatments were sometimes repeated for recurrences of the disease Smaller joints responded better than large joints Copeman³⁰¹ approved the use of histamine by subcutaneous injection as well as by iontophoresis For unstated reasons "active rheumatoid arthritis" was considered a contraindication Levant³²⁰ checked the physiologic reactions of iontophoresis with histamine against that with controls (tap water and four other solutions) All produced superficial hyperemia, but therapeutic results were obtained only with histamine Several patients with "arthritis" were benefited (In most of these papers the classification of arthritis was completely inadequate Practically no control studies were made on patients treated otherwise—Ed)

Harpuder³³⁰ demonstrated the production of vasodilating substances (histamine and acetylcholine) in the skin during physical therapy

Concentrated Viosterol Vitamin D in Massive Doses Two arthritic patients on massive doses of vitamin D for hay fever, as prescribed by Rappaport and Reed (1933, 1934), noted improvement in their joints Dreyer and Reed³³¹ therefore gave similar large doses to arthritic patients Of 34 patients with atrophic arthritis, 25 were "improved" Patients with hypertrophic arthritis and with "arthralgia" were also improved Improvement was first noted, in some cases, after a week, in others after six months' treatment The disease was apparently "controlled," not cured, for although many became symptom-free and had no recurrences in 18 months, others had mild recurrences when administration of the drug was stopped Patients were given doses of 200,000 USP or international units of vitamin D (concentrated viosterol) daily for one month If relief was noted the dose was never increased, otherwise, the dose was increased by 50,000 to 60,000 units each week until improvement or overdosage was noted In stubborn cases patients were given 600,000 to 1,000,000 units daily for a few days and then put back on 200,000 units daily The majority received relief on 300,000 to 500,000 units daily

Tolerance of patients to the drug varied greatly Toxicity occurred more often after prolonged use of smaller, than the short use of larger, doses Symptoms of toxicity were persistent nausea, frequency of urination (with or without polyuria), lassitude, anemia, polydipsia, diarrhea, vomiting, and abdominal pain Blood calcium sometimes rose to 25 to 30 mg per 100 cc often without symptoms To prevent or combat toxicity, 6 gm of brewers' yeast were given three times a day with frequent success When signs of toxicity appeared, administration of the drug was discontinued for two weeks with disappearance of symptoms Then the drug was continued in nontoxic doses Conclusions from studies on humans and animals were that concentrated vitamin D in the doses used is not hazardous if signs of early toxicity are recognized and the drug is stopped Persistence in administration might lead to permanent effects, even death

Patients on this treatment for two to five years for other diseases showed no hypertension or other ill effects (The report is conservatively written, but apparently controls were not studied. Since a "control" and not a cure was obtained, auxiliary treatment such as physiotherapy was advised. In a recent communication Reed²¹² stated that they are now using no more than 300,000 or 400,000 units daily. Vrtiak and Lang³³² have treated 20 patients with atrophic arthritis, 12 [60 per cent] were improved, 8 were not. Results were considered not unlike those with other methods and indicated that a conservative attitude toward such therapy should be adopted.—Ed.)

Rest and Movement The virtues of systemic rest have been stressed as the most important part of treatment^{251, 253, 333}. Prolonged rest in bed is necessary for acutely swollen joints, for which splints or casts may also be required to make rest absolute. In chronic cases the problem is not one of rest versus exercise but of rest and exercise. The patient may overdo on rest, with resultant atrophy and ankylosis, but the majority overdo on exercise to "keep the joints limber"^{307, 318, 334}. In chronic cases some exercises, including bed-exercises, are necessary to preserve joint function and muscle tone, but not that amount which causes more pain²⁵². Therapeutic exercises for various joints were described in detail by Coulter and Molander³³⁵.

Physical Therapy Medicines, vaccines, and diets for arthritis gain and lose their popularity but centuries of use have proved the value of physical therapy. Many physicians do not understand its advantages, hence there is a scarcity of trained physiotherapists. In Massachusetts there are about 22 arthritic patients for every physician, but about 70,000 patients receive no treatment whatever (Ober²⁹). Physiotherapy is justly or unjustly held in disrepute for reasons listed by Behneman³³⁶. Indications for, and methods and results obtainable by physical therapy have again been reviewed^{337, 338, 339, 340, 341, 342}. Whenever possible the arthritic patient should receive physical therapy in three ways: (1) by daily home measures used by the patient himself^{335, 343}, (2) professional physiotherapy three or more times a week from technicians or physicians trained therein, and (3) annual or semi-annual visits to a spa or other institution for treatment combined with the advantages of a vacation (Aldred-Brown,³⁴⁴ Holmes,³⁴⁵ and Lautman³³³).

To supplement the limited sessions of professional physiotherapy which patients can afford, the intelligent ones and their relatives should be fully instructed in simple home methods. Thus the cost of the patient's care can be reduced and the physician can control the patients over long periods necessary for treatment. By demonstrations and mimeographed sheets Coulter²⁹ teaches his patients optimal types and amounts of heat, massage and exercises, and the use of cheap but effective electric bakers, whirlpool baths and appliances for harmless exercises.

(Few spas attempt to teach patients simple home methods of physical therapy which would permit their advantages to be projected into the patient's home environment. Seventy-five per cent of patients seen by one of us had previously consulted

cultists, generally because little or no physiotherapy was prescribed by physicians Unless the better types of professional and home physiotherapy are more fully utilized by physicians, patients will continue to flock to the spine and foot twisters —Ed)

Before "home-physiotherapy" can be safely prescribed, physicians themselves must learn its principles and methods, and when it is given it should always be under a physician's general supervision (Ober³⁴⁶) Uses and physiologic effects of heat were thoroughly reviewed by Pemberton³⁴⁷ and Fox³⁴⁸ Diathermy, approved by many, may be harmful in cases of atrophic arthritis with much demineralization of bone, according to Holbrook and Hill³⁰² (No proof of this is given—Ed) Pelvic diathermy is particularly useful for pelvic foci of infection (Robinson^{306, 310}) Cold or hot Epsom-salt packs are often very analgesic³⁰² Hot paraffin packs deserve wider use^{302, 307} Thermal baths and douches, and Fango (mud) packs have their protagonists^{350, 351, 352} Short wave therapy for chronic arthritis was approved by several (Berry,^{353, 354} Bierman and Schwarzschild,¹⁸ Kobak,⁸⁰ Torbett,⁷⁹ Wilson^{355, 356, 357}) The effect of short wave diathermy is about the same as that of ordinary (long wave) diathermy, according to Kovacs,³²⁷ but the former can be used in regions where electrodes cannot well be applied Kling⁷⁸ tabulated reported results from short and ultra-short wave therapy for "chronic arthritis", of 146 patients 80 per cent were improved Of his own 29 patients 72 per cent were improved Results were best with the 23 meter wave

Heliotherapy is often harmful for patients with rather acute arthritis or with fever Dizziness, nausea, vomiting and fever may result (Holbrook and Hill,³⁰² Jones³³⁴) Massage is over-rated and alone is useless, according to Jones³³⁴, others stress its importance Physical exercises can be reproduced easily and painlessly by sinusoidal currents³³⁴ Underwater therapy offers an unequalled means of preventing and correcting adhesions and of increasing muscle and joint function^{333, 358 359, 360} Occupational therapy has special advantages distinct from those of physiotherapy³⁶¹

Roentgen Therapy Results of roentgen therapy in "acute and chronic non-specific infectious arthritis" were "gratifying" according to Garland,⁴⁰ although not as striking as in gonorrheal arthritis Nine patients with "acute infectious arthritis" were treated four became symptom-free, two improved Of 13 patients with joints irradiated in these cases, six became symptom-free, two improved Three patients with "chronic infectious arthritis" were treated two became symptom-free Of 10 joints treated, three became symptom-free, six improved Scott³⁶² approved radiotherapy, but King³⁶³ considered it of little value An analgesic, not a curative effect, is more frequent in acute than in chronic cases

Fever Therapy Results of fever therapy for atrophic arthritis have been satisfactory to some (Kobak⁷⁴), disappointing to the majority They are not nearly as good as in gonorrheal arthritis Hensch, Slocumb and

Popp⁴⁸ tabulated results given in the first 15 reports thereon (1931-1934) of 147 patients, only 7 per cent were "cured" or completely relieved. Of 60 patients treated by Hench, Slocumb and Popp, none was cured, 18 per cent were markedly, and 12 per cent moderately benefited, and 70 per cent received little or no relief. At the Fifth Annual Fever Conference (May 1935) results in 129 more cases were reported (Hefke,^{45 51} Stecker,⁴⁵ Strickler,^{45, 53} Tenney and Snow⁴⁵). Summarizing all published reports, the earlier optimistic and later conservative ones, Hench⁵⁶ found that of a total of 315 patients with chronic atrophic arthritis treated by fever, only 5 per cent became symptom-free, 25 per cent were notably relieved, but the rest received little or no relief. Results were a little better in cases of acute atrophic arthritis: of 21 patients, 10 per cent seemed completely relieved, 40 per cent notably benefited.

Recently Short and Bauer⁵¹ gave 71 fever sessions with general diathermy to 25 patients, 80 per cent showed temporary improvement, but in only 20 per cent was this maintained until the follow-up 6 to 41 months later. None were harmed but all looked on it as a harrowing ordeal. Balancing results against the treatment's severity, Short and Bauer concluded that it was only occasionally justified and should not be used to the exclusion of other treatment. Rogers³⁶⁴ noted benefit in one case. The use of low temperatures (101° F. for 3 to 5 hours) was recommended by Atsatt and Patterson^{47, 73}. Simpson⁴⁵ and Shands⁴⁵ felt that artificial fever therapy given just before or after orthopedic manipulation of deformities increased the results of manipulation.

Malarial (fever) therapy was given to 13 patients by Cecil, Friess, Nicholls and Thomas³⁶⁵. All received immediate, sometimes striking, benefit, but, six months later, only one was symptom-free, a patient whose arthritis was of only four months' duration. In 12 cases the arthritis relapsed, in eight completely, to its original state, in four partially. (One of us, P. S. H., gave malaria to a patient with severe atrophic arthritis in 1928; only a temporary, partial remission resulted.—Ed.)

Surgical Procedures 1. Sympathectomy. Sympathectomy was performed in five cases of "chronic arthritis" with hyperhidrosis and vasomotor disorders in affected limbs. Results were reported by Ross³⁶⁶. Two of three patients whose arms were affected "derived great benefit". In one of two patients whose legs were affected "the treatment was successful in relieving pain and restoring function" (No further details were given). De Takats³⁶⁷ considered sympathectomy of unproved value in chronic arthritis. In an unstated number of Boots' cases,³⁴ poor, as often as good, results were obtained. Unilateral lumbar sympathectomy was performed by Kinsella³⁸ in "about 35 cases" to study results on one leg. The first results were very good, but subsequent results did not justify continuance of the procedures. Relief of pain and increase of motion were not constant. Several papers on physiologic reactions after sympathectomy are of interest.^{368 369 370 371, 372}

2 Splenectomy was recently performed in two cases of "Felty's syndrome" (Hanrahan and Miller, 1932, Craven, 1934), only temporary improvement was noted. Miller and Craven have since notified Fitz²⁶ that the patients died 14 and 18 months after operation.

3 Thyroidectomy is said to benefit the joints of arthritic patients with hyperthyroidism. (This relationship has been discussed previously—Ed.) Bach²⁰⁷ noted marked improvement in one case immediately after operation.

4 Parathyroidectomy. Also previously mentioned was the supposed relationship between the parathyroid glands and polyarthritis and the reported relief of arthritis by parathyroidectomy. Schkurov²⁹⁸ performed this operation in 83 cases of "chronic rheumatic polyarthritis and spondylarthritis." The results and other reports concerning arthritis and the parathyroids will be discussed later.

5 Orthopedic procedures. Synovectomy is done by some orthopedists for active polyarthritis, by others only for persistent monoarthritis of knees unresponsive to other treatment. Radical synovectomy of knee joints may remove an infected focus and pathologic debris which interferes with partial restoration of function. Ankylosis rarely supervenes. Restoration of considerable function resulted in the few cases currently reported^{15, 19, 252, 273, 374}. Several reviewed the indications, methods and results obtainable by various procedures for the correction and prevention of deformities: traction, casts, splints and supports, tenotomies, osteotomies, capsulotomies, arthroplasties, fusions, manipulations^{10, 20, 21, 102, 153, 318, 331, 371, 375, 376}. Manipulation is particularly emphasized as a valuable method used insufficiently^{19, 318, 377, 378, 379}. Reconstructive surgery is not indicated until the arthritis has been inactive at least six months³⁸⁴. A chain for patients with bilateral ankylosis of hip joints was described (Kuhns³⁸⁰).

Prognosis, Remissions and Results of Treatment. A patient with atrophic arthritis (or any other kind) will follow one of four life courses according to Nissen³⁸¹. Of 500 cases of arthritis studied by him from the onset of the disease until the patient "ended with 'hic jacet'," 208 cases were classified "rheumatoid-genuine arthritis with actual destruction, partial or complete." Of these cases only 2 per cent followed course A (an initial attack and full recovery to the former level of activity), 32 per cent followed course B (remissions, relapses, and a slow steady decline in functional activity), 56 per cent followed course C (a drop to a low level of functional activity in a variable period of time, the patient remaining at that low level for the rest of his life), 10 per cent followed course D (a steady downward course from the onset of disease to death).

According to Dawson¹⁰³ about 25 per cent of patients "recover," 50 per cent "improve" or their condition becomes "quiescent," and 25 per cent become progressively worse. Of Pemberton's²⁵³ 300 patients with atrophic and hypertrophic arthritis (types not analyzed separately), 6 per cent were "cured," 32 per cent "greatly improved," 57 per cent "definitely improved."

"The figures were almost exactly the same for both the atrophic and hypertrophic types of arthritis." Results for Lang's²⁵⁰ 100 patients were 60 per cent improved, of which 43 per cent were "markedly improved." The patient's cooperation in treatment is of paramount importance. Of those who improved markedly, 90 per cent were persistent and cooperative in treatment, of those who did not improve, 64 per cent were uncooperative, discontinuing treatment within six months.

As a rule atrophic arthritis becomes inactive relatively slowly (within weeks or months) even under the most successful treatment. Neither preliminary nor final remissions appear abruptly within a few hours. Particular significance may therefore be attached to the dramatic sudden remissions that may accompany intercurrent jaundice. Hench (1933-1934) reported the "analgesic effect" of intrahepatic jaundice on 16 patients with atrophic arthritis, fibrositis and sciatica. Since then he has studied many more such cases in which sudden remissions accompanied jaundice of different types.⁴⁰ An example was given: a woman aged 49 years, had periarticular fibrositis and atrophic arthritis for three years, which developed so that she was unable to turn a doorknob, squeeze a wash cloth, or grasp a tumbler. A febrile laryngitis developed for a few days. Ten days later she awoke to find herself jaundiced and completely free of all signs and symptoms of rheumatism. Details concerning the physical and chemical examinations during the remission were given. For several months the patient was completely free of symptoms, then the disease began to return. In the majority of such cases the remission was complete and lasted weeks or months, occasionally longer. These observations indicated to Hench that the clinical pathology of atrophic arthritis is probably much more reversible (and more rapidly so) than was heretofore evident, and led to the hope that an intensive study of this phenomenon may eventuate in a method of treatment similarly dramatic and prompt.

HYPERTROPHIC ARTHRITIS

Definition. Most roentgenologists who see any overgrowth of bone in roentgenograms in a case of articular disease make a diagnosis of "hypertrophic arthritis," and if bone overgrowth is absent, the diagnosis is apt to become "atrophic arthritis" (Pemberton²⁹). Radiologists must exhibit a more informed type of scrutiny and become familiar with the variable pathologic and clinical aspects of the different arthritides to interpret roentgenograms more correctly. The clinical definition of "hypertrophic arthritis" is (or should be) quite different from the radiologic definition of "hypertrophic arthritis." Roentgenographically there are several different types of hypertrophic arthritis, such as that seen in certain traumatized joints, or those types found in certain stages of gouty, gonorrheal, atrophic and other forms of arthritis (Haden,²⁹ Doub,¹¹ McMurray¹⁰). To the clinician, however, hypertrophic arthritis means (or should mean) one particular disease, one special type of arthritis. The various forms of arthritis in which the roentgenographic changes of hypertrophy of bone are

but a minor feature, an incident compared to more obvious clinical features (acute trauma, acute gout, gonorrhea, and so forth), might be called "secondary hypertrophic arthritis." Thus they are distinguished from "primary hypertrophic arthritis," the clinical syndrome synonymous with "senescent," "degenerative" or "osteo-arthritis" in which, in the absence of a known cause or more striking clinical features, roentgenographic alterations constitute the most consistent and outstanding feature of the disease and give it a name (Haden ²⁰)

Incidence Studies of knee joints of persons from the first to the ninth decade of life indicate that after the age of 30 years the degenerative changes that lead to hypertrophic arthritis were found with increasing frequency, so that by the fifth decade all knee joints were so affected (Keefer ³⁶² also 1933, 1934, Bauer and Bennett ²⁹ also 1933)

(Radiologic and pathologic studies by others have indicated that hypertrophic spondylitis is also present in practically all patients aged 50 years or more—Ed)

The sex incidence is about equal (Dawson ¹⁰²), but the fingers, knees and cervical spine are more commonly affected in women, the lower part of the spine and hips in men

Symptoms and Course Although the disease is almost universal in persons more than 50 years of age, only about 7 to 10 per cent of its victims have significant symptoms (Keefer, Parker, Myers and Irwin, 1933, 1934) Those with symptoms fall into three groups (1) the obese, whose traumatized weight-bearing joints early proclaim their hypertrophic arthritis, (2) mechanics and workers in occupations in which trauma elicits painful symptoms, (3) hypersensitive persons (generally females) whose pain perceptions are augmented (Hench ¹⁰⁶) Symptoms rarely appear before the age of 40 years, usually after the age of 50 They may appear before the age of 40 in females who have experienced a premature or artificial menopause or in persons subject to some unusual forms of long continued trauma (Dawson ¹⁰³)

Symptoms are not always confined to joints Just as every case of atrophic arthritis has some associated fibrositis, so in hypertrophic arthritis, fibrous tissue may share the pathologic process of degeneration (Howitt ²⁶³) Neuritic and muscle pains and stiffness ensue

(Symptoms of this senile fibrositis—fatigue, loss of muscular resiliency, chilliness and vague muscle pains—are so universally present in senility that Pennington, 1934, was of the opinion that "senility is practically synonymous with fibrositis"—Ed)

Small gelatinous cysts occasionally appear, attached to tendons near a Heberden's node (Hench ¹⁰⁶) They are often opened "to let matter out" This is generally unnecessary, they may recede spontaneously Occasionally they become inflamed After they are opened, the walls collapse and the unsightly nodule recedes, though it may reform

(These have escaped general notice and description. Photographs of them are in reports of Hench¹⁰⁰ and of Nachlas (1932). The latter studied 28 specimens thereof, generally over the terminal phalangeal joints of hands affected with Heberden's nodes. In one of Hench's cases the cystic nodule was over a midphalangeal joint. According to Nachlas the mucoid or gelatinous material therein may contain excess calcium in solution but no urates, and if unremoved, the nodules eventually solidify to form genuine bony Heberden's nodes—Ed.)

Röntgenograms Radiologic features were reviewed by Doub¹¹. As before noted, those seen in cases of "traumatic hypertrophic arthritis" in young persons subjected to severe acute or chronic trauma may resemble those of "senescent hypertrophic arthritis" (degenerative, osteo-arthritis) in relatively non-traumatized joints of the elderly (e.g., distal phalangeal joints). Cases of polyarticular "hypertrophic arthritis" are more likely to represent senescent hypertrophic arthritis than cases of chronic monoarticular "hypertrophic arthritis," as these latter may represent old traumatic arthritis, such as ensues in hips after Perthe's disease or osteochondritis or following slipped femoral epiphyses in childhood^{10, 11}. Thus the average age in McMurray's¹⁰ cases of bilateral hypertrophic arthritis of hips was 53 years, in cases of unilateral hypertrophic arthritis of a hip it was only 34 years and there was a frequent history of childhood injury. Therein lies further evidence of the necessity for distinguishing between the clinical syndrome of (senescent) hypertrophic arthritis, which is one disease, and "hypertrophic arthritis" in the radiologic sense which is not a disease per se but a radiologic feature of several diseases.

Pathology The articular pathology in hypertrophic arthritis, reviewed by Keefer³⁸² and Parker and Keefer²⁵⁶ was so different from that of atrophic arthritis that the idea that the two diseases are the same seemed untenable. Muscles, tendon sheaths and fascia, with their small blood vessels, also participate with joints in the general state of fibrotic thickening, according to Howitt²⁰³.

(The pathology of this associated "senescent fibrositis" is not described further. As has been done for joints, studies on the histology of muscle and fibrous tissue at different age periods should be made to clarify the pathology of senescent, as contrasted to other types of, fibrositis, and to explain the "stiffness of age"—Ed.)

Laboratory Data Marked anemia is not a feature of hypertrophic arthritis. Gray, Bernhard and Gowen²⁶⁹ found the erythrocyte count below 4,000,000 per cu mm in only 16 per cent, and the value for hemoglobin below 70 per cent in only 6 per cent, of cases of hypertrophic arthritis. Hemoglobin was normal (over 14 gm) in 11 of Collin's²⁶⁸ 23 cases, between 12 to 14 gm in 11 cases, below 10 gm in only one case. The Schilling count was shifted to the left (an increase in percentage of younger neutrophils) in only 17 per cent of Steinberg's²⁷⁰ cases of hypertrophic arthritis, but in 78 per cent of his atrophic cases. The percentage of younger neutrophils was less than four in most cases of the former, above four in most of the latter. There was a general correlation between Schil-

ling counts and sedimentation rates the latter were usually below 0.35 mm per minute in hypertrophic, above 0.35 mm in atrophic arthritis (Rourke and Einstene method) Gray²⁵¹ found the sedimentation rate (Westergren method) over 20 mm per hour in only 2 per cent, 10 mm or below in 85 per cent. Essentially similar rates were noted by others^{29, 34}

No relation between anemia and gastric acidity was found by Collins²⁶⁸, only one of 11 cases had reduced gastric acids. Of 35 cases, achlorhydria was found by Hartung and Steinbrocker²⁷² in 26 per cent, hypochlorhydria in 3 per cent (subacidity was 17 per cent more frequent in atrophic arthritis)

Values for total blood protein, globulin, albumin and plasma fibrinogen were normal in Davis'²⁹ cases of hypertrophic arthritis (generally abnormal in atrophic arthritis). Alterations in blood proteins were found by Aldred-Brown and Munio²⁶⁷ when patients with hypertrophic arthritis (group 1) were compared to healthy young normals (group 2), but these differences tended to disappear when they were compared to non-rheumatic persons of less favorable economic status (group 3). The average values (gm per 100 cc of plasma) were as follows. In groups 1, 2 and 3, respectively albumin 3.91, 4.51, 4.09, globulin 2.32, 1.69, 2.13, fibrinogen 0.34, 0.16, 0.22, total protein 6.35, 6.37, 6.35. Thus plasma protein was low in hypertrophic, but not so low as in atrophic, arthritis.

Hartung and his associates^{258, 259} found a tendency towards an elevated plasma cholesterol and a lowered serum calcium. Of 59 cases, 62 per cent had high, 3 per cent low, and 35 per cent normal, values for cholesterol (160 to 230 mg). The mean total cholesterol was 235.4 ± 45 mg. Values for the mean and standard deviation of serum calcium were 9.986 ± 0.616 mg per 100 cc (normal 10.241 ± 0.647 mg). Race²⁶⁰ noted a slight but definite tendency towards lower values for serum calcium in atrophic than in hypertrophic arthritis. Serum magnesium was essentially normal in hypertrophic and atrophic arthritis (a little lower in the latter). Blood groups were as in normals. There was no characteristic deviation in urinary acidity.

Etiology and Pathogenesis Various writers have blamed each of the following factors as the sole cause of the disease: heredity, constitution, the degenerative processes of age, chronic trauma, circulatory disturbances, some specific metabolic fault, an endocrine disturbance, infection. Others believe that not one factor, but a combination of factors is responsible—particularly age plus chronic trauma. Still others believe there is one specific cause, as yet unknown, and that those mentioned are merely predisposing, precipitating, or accelerating factors of secondary importance.

Factor of Heredity and Constitution Heredity is commonly blamed because patients state the disease "runs in the family."¹⁰³ Its incidence, however, is so general that practically all one's ancestors over 50 years of age had it. Others blame heredity not for the disease's general incidence as much as for its premature appearance. "Some patients inherit better cartilage than others. The poorer the inheritance and the greater the endogenous

and exogenous trauma, the earlier will hypertrophic arthritis develop" (Bauer and Bennett ²⁹) Pribram and Fahlstrom ²⁶¹ are current sponsors of the idea of a constitutional tendency of brachymorphics for the disease, but many of Pemberton's ²⁵³ patients were slender

Factor of Tissue Degeneration (Tissue Age) One's calendar and histologic ages are of course not identical. Furthermore, because of differences in the histologic "ages" of various organs, one's mental (cerebral) and general physical ages may be quite different. The majority believe that the histologic age of cartilage (age being the sum total of all traumatic and toxic insults of life) is the chief determinant of the disease. Hypertrophic arthritis represents a localized, premature senile change which may occur in clerks as well as bricklayers, from mental as well as physical overstrain (Howitt ²⁶³)

Factor of Trauma To some, "age" is but the sustained opportunity for mild long-continued articular trauma as a result of posture, obesity, occupation or recreation. They regard the disease as the result of such chronic trauma, or that from intra-articular or juxta-articular fractures with faulty alignment, unreduced dislocations, foreign bodies or other orthopedic disabilities ^{13, 279, 283}. Doub and Jones ¹² related the disease to chronic but not to acute trauma since single severe trauma (juxta-articular fractures) seemed to play no rôle in the production of hypertrophic arthritis.

Factor of Circulatory Alterations Circulatory deficiencies (arteriosclerotic, inflammatory, or vasospastic) leading to excess articular catabolism have been held responsible. However, no evidence is at hand that the nutrition of a person's osteo-arthritic joints is more deficient than that of his unaffected joints, or that there is more arteriosclerosis of nutrient vessels of the former than of the latter ¹⁰³.

Factor of Altered Metabolism In contrast to the idea of a nonspecific metabolic defect from poor articular circulation is the theory that some more or less specific metabolic derangement is responsible, a disturbance in utilization of sugar, of calcium, of sulphur. A defect of the last type is now a popular notion, and some believe that hypertrophic as well as atrophic arthritis is due to a deficiency of sulphur in the body, particularly in cartilage ^{255, 284-286, 288, 289}. The majority have made no attempt whatever to differentiate the types of arthritis in which they found reduced cystine in nails or which improved on sulphur—merely labelling them "arthritis" or "chronic arthritis". Wheeldon ²⁵⁵ noted that the average cystine content of nails was a little lower and rose higher after treatment in hypertrophic, than in atrophic, arthritis. Senturia ²⁸⁷ found no abnormal urinary excretion of sulphur in either type.

(It is impossible for a critical reader to form any conclusions when even the types of arthritis treated are not differentiated—Ed.)

Some are still keeping alive the notion that the disease is related to a purine disturbance since "the blood uric acid is always increased" ²⁹⁵. (This has long since been disproved by numerous careful investigators—Ed.)

Todd²⁹⁰ "slightly" incriminated "the hepatic factor," and Miller²⁹¹ noted hepatic dysfunction (an altered levulose tolerance) as often in hypertrophic as in atrophic arthritis (in about a third of each group)

No causal relationship between hypertrophic arthritis and any metabolic disturbance associated with diet was found by Bauer²⁹⁴ or by Hall and Myers²⁹². According to Langstroth³¹⁶ the relationship of the disease to diet is a paradoxical one, although there is no evidence that its victims have eaten less "protective foods" than others, the administration of such foods is of value

Factor of Endocrine Disturbances Although the disease frequently becomes symptomatic near the menopause, no definite connection between it and endocrine glands has been proved. Since hypertrophic arthritis occurred in only 17 per cent of 414 cases of hyperthyroidism, no relationship between these two diseases was apparent to Monroe²⁹⁰. However, of 98 patients with myxedema, 33 per cent had hypertrophic arthritis, "an intimate and important association". Their average age was 51 years, but myxedema and not just age was considered the major factor

Of Haden's²⁹ 50 cases of hypertrophic arthritis, a "low" metabolic rate was found in 84 per cent, an accelerating factor considered important

(Many others, e.g. Race,²⁹⁰ considered metabolic rates to be normal—Ed)

Factor of Infection The factor of infection seems unimportant to the majority²⁹. There is little or no direct evidence of infection, and various immunologic reactions used as evidence of the infectious nature of atrophic arthritis are usually absent in hypertrophic arthritis. Blood cultures by Gray²⁵¹ in 79 cases were all negative for streptococci. Agglutinins to hemolytic streptococci were not found by Dawson¹⁰³. They were rarely found by Gray, Bernhard and Gowen²⁶⁰ in significant amounts (1:160 or higher) they were present in low titer (0 to 80) in 83 per cent of cases, in a titer of 160 to 320 in 17 per cent, none in higher dilutions. In only three of Blair and Hallman's²⁹⁰ 16 cases were agglutinins to Cecil's "typical" streptococcus found in dilutions greater than 1:160. Antistreptolysins in abnormal amounts (over 100 units) were found in only two of 13 cases of "chronic arthritis other than rheumatoid". Skin reactions to hemolytic and green streptococci were absent in four, present in six cases of Wainwright²⁷⁸. One patient reacted to two strains, two patients to three strains and three to five strains or more

(No interpretation was offered—Ed)

Some believe, however, that infection plays a contributory rôle. Pemberton²⁵³ reported two cases: one patient responded "immediately" to the removal of infected teeth, suggesting that infection played a rôle, and the other to rest, diet and improved intestinal function, suggesting that age alone was not responsible. The difference between a painful joint with hypertrophic arthritis and a painless one roentgenographically even more hyper-

trophic, is generally thought to be the factor of trauma, but Sherwood³⁰³ agreed with Key (1933) that low grade infection may produce pain in joints which would otherwise be symptomless. Bauer²⁰ ascribed the variable presence of pain to changing pathology. When marginal osteoid tissue proliferation is occurring, periosteum may become elevated and pain results. When this osteoid proliferation ceases and the tissue becomes calcified pain may stop.

Treatment Perhaps the most important part of treatment is to explain to the patient the differences in the nature, particularly in the prognosis, of the disease he actually has from that which he thinks he has, and to assure him that hypertrophic arthritis (unlike atrophic, "deforming arthritis" which he fears) is not essentially an ankylosing, severely-crippling, progressive disease. This done, many patients neither ask nor accept other treatment but bear their difficulty philosophically without the "nuisance of treatment" (Hench¹⁰⁶).

Rest and Reduction of Trauma Many patients are deliberately over-exercising under the erroneous impression that "unless the joints are kept active they will stiffen." With the onset of symptoms of hypertrophic arthritis patients often go out of their way to activate the joints, "to keep limber," grimly determined to keep going. This only irritates the process and is harmful and unnecessary, as ankylosis is not characteristic of the disease. Generous rest and the reduction of trauma are highly desirable, although not to the extent that the patient feels himself a crippled invalid^{13, 106, 253, 283}. Extra hours of rest at night and in the daytime, reduction of obesity, and the use of a cane, corset or roller bandage, will minimize trauma and permit a patient to be comfortable when he is active.

Diet Reduction of tissue edema and relief by means of the mild, dehydrating effect of a low-carbohydrate, low-calorie diet were noted by Scull and Pemberton^{314, 315} in hypertrophic, as well as in atrophic, arthritis. Others found no special dietary indications for the disease except for the reduction of obesity^{292, 294}.

Removal of Foci This has seemed useless in the majority of cases, though it may be indicated in particular instances^{253, 304}.

Vaccines Vaccines are generally not prescribed. Sherwood^{303, 309} treated 260 patients with various vaccines with results which were considered as good as those obtained in atrophic arthritis.

(He stated that neither the severity of symptoms nor the type of arthritis influenced the results from vaccine. This experience is at variance with that of the majority and makes one doubt the value of the vaccine, particularly when a definite, if smaller [33 per cent], number of controls improved on saline injections—Ed.)

Young,³⁸³ an associate of Crowe, used the latter's vaccine "successfully" in treatment of 100 cases of "osteo-arthritis." Contrary to what is customary, their plan is one of progressively *smaller*, not larger, doses of vaccine. McCarty³²⁵ also considered (intravenous) vaccines helpful for pain, but less so than in atrophic arthritis.

Sulphur Relief from injections of sulphur was reported in hypertrophic as well as in atrophic arthritis²⁵⁵ Good results ensued "in every case" (five) in one series,^{285, 286} in 50 per cent of another series (26 cases),²⁸⁴ but in only three of eight cases in a third group³²¹

Gold Injections Such injections were used in the hypertrophic type also In a series of 17 cases, Pemberton³²³ (Liverpool) noted much improvement in 24 per cent, improvement in 13 per cent For intractable osteo-arthritis Slot⁴² combined the use of gold with epidural injections of procaine Foestier⁴¹ found gold of no value in osteo-arthritis

Iontophoresis with Vasodilating Drugs Of 25 patients treated with histamine by Kling¹⁷ 60 per cent improved Of 29 patients treated with mecholyl by Abel³²⁰ 90 per cent had relief of pain, Kovacs,³²⁷ however, noted no relief with mecholyl

Miscellaneous Thyroid extract was used by some¹⁰³ Relief of pain was obtained by Foestier³⁸¹ with local injections of lipiodol (perineural, peri-articular) Ten of 18 patients improved while on large doses of vitamin D (concentrated viosterol) (Dreyer and Reed³³¹)

Physical Therapy This, of course, is extensively advocated Underwater therapy is especially valuable for elderly patients with hypertrophic arthritis³⁵⁸ Some advocated short-wave therapy^{79, 354, 356} Diathermy was particularly approved by Kovacs³²⁷ Roentgen therapy was used by Garland⁴⁰ in seven cases of hypertrophic spondylitis only one patient became symptom-free but four "improved" Fever therapy is cautiously approved by some,^{47, 73} considered of no value by others,^{51, 74} Tenney and Snow noted improvement in only four of 10 cases³⁸⁵ Various other physicians have treated a total of 74 patients only 4 per cent became symptom-free, about 50 per cent noted some relief⁴⁸

Orthopedic Treatment Considerable relief may result from manipulation in selected cases, such as osteo-arthritis of the cervical or lumbar spine, or hip^{10, 318, 334, 377, 379} Synovectomy may help some patients greatly^{334, 373} Bone puncture (Mackenzie, 1931-1932) relieved a few, failed in other cases⁹⁹ Cheilotomy to remove femoral osteophytes has not been very successful and is inferior to hip joint resection³³⁴ Because bony union is difficult to obtain, arthrodesis is less useful than reconstruction of hip joints

BACKACHE AND SCIATICA

Backache and sciatica are not, of course, diseases per se but symptoms of many diseases The anatomic physiology of the spine and its adjacent tissues is so complicated that experienced orthopedists at times have great difficulty in determining the cause of backache or sciatica The physician without at least some orthopedic training is even more confused He is apt to examine the spine for rather gross stiffness, look for spurs in roentgenograms and, if there is a poker spine, the diagnosis becomes "ankylosing spondylitis" (or an equivalent term) If there are spurs the diagnosis

becomes "hypertrophic spondylitis" If neither is present the diagnosis becomes simply "backache" Going a little farther, he may offer a favorite explanation "backache due to poor posture," from "uterine displacement," from "strain" or "fatigue"

The literature reviewed contained about 50 articles on, and about as many classifications of, backache Backache can be briefly classified as being from (1) primary neurologic conditions, (2) genito-urinary disease, (3) gynecologic disturbances ("post-pregnancy backache," etc.), (4) metastatic malignancy, and (5) "orthopedic conditions" Commoner orthopedic conditions which produce backache are postural or occupational strain of muscles and ligaments, infections of ligaments, muscles and their fibrous tissue (toxic or infectious "myofascitis" or "paravertebral fibrositis"), developmental anomalies of the fifth lumbar and first sacral region, disturbances of the intervertebral disks, and (traumatic, infectious or degenerative) arthritis of the vertebral bodies or articular facets, or both

The lower back is a common site of symptoms in the malingerer, be it the industrial worker seeking compensation or the tired housewife seeking sympathy Points useful in detecting malingering were listed by Stuck³⁸⁶ To be determined are (1) an estimate of the patient's sincerity of purpose from his general demeanor, (2) whether his general body build and posture (tall, thin), or his occupation are such as to make him liable to injury, (3) a reasonable consistency between the severity of the injury and that of symptoms (In general there is a correlation between the two, although there are exceptions and trivial injuries may induce severe backache, and only mild damage may result from a violent accident), (4) the relationship between the time of injury and the onset of symptoms (as a rule symptoms appear within a few hours), (5) presence or absence of previous backache, (6) in the presence of organic disease examination will generally reveal muscle spasm, sometimes scoliosis, it being difficult if not impossible for a malingerer to feign muscle spasm or scoliosis except momentarily, (7) with organic disease, tender spots remain rather consistently localized during the first and subsequent examinations, malingerers rarely recalling the sites of previous "tenderness" carefully enough to avoid detection, and (8) the newer technic of making roentgenograms (Ghormley and Kirklin, 1934) will reveal disease of facets as well as of vertebral bodies

The technic and significance of various manipulative methods of examining the back to localize disease of the spine were reviewed by several³⁸⁶⁻³⁹⁶ Some considered the physical examination much more valuable in certain cases than roentgenograms because the latter may reveal changes (spurs, anomalies) which may or may not be related to the presenting symptoms Without careful investigation symptoms must not be too readily blamed on the hypertrophic lipping so commonly seen in laborers and in the obese over 40 years, and in others over 50 years of age

Comments on Differentiation Figures on the percentage of cases of

backache from arthritis are not always reliable as they are often colored by a physician's special knowledge or lack of it. If in a given case pelvic disease is present, a gynecologist may blame the backache thereon without seeking a further explanation, if pelvic disease is absent he may rightly or wrongly dismiss the case as of "rheumatic origin." The practitioner may blame poor posture in a case when roentgenograms of the spine are apparently "negative." (The word "apparently" is used advisedly as, too often, roentgenographic examination is limited to an antero-posterior view of the spine, and lateral and oblique ["three-quarter"] views are not taken—Ed.) Of 63 cases of backache seen by Shafiroff and Sava³⁹⁷ 70 per cent were from "arthritis," of which 50 per cent were ascribed to "traumatic arthritis of facets," 39 per cent to "lumbosacral and sacro-iliac osteoarthritis," and 11 per cent to "generalized arthritis." They concluded that in backache from pelvic disease the pain was likely to be diffusely spread over the back and referred anteriorly to the legs from pressure on iliohypogastric, ilioinguinal, and femoral nerves, but that in backache from osseous disease, pain is more localized to the affected area and is projected generally along the posterior portion of the leg from pressure on sacral nerves.

(The data given are inadequate for the reader to accept fully the diagnoses and differentiation—Ed.)

In differentiation Gotten³⁹⁸ characterized the pain of lumbosacral myositis as being usually aggravated by cold or damp and partially relieved by exercise, while that of arthritis is aggravated by exercise. Of the common types of backache—traumatic, infectious, and static or attitudinal—the last constitutes 90 per cent, according to Davidson and Horowitz,³⁹⁹ and frequently leads to microtraumatic arthritis. Certain differences were noted by Magnuson³⁹⁹. Pain which is worse in the morning on rising, but disappears after brief activity is frequently due to "peri-arthritis" of paravertebral ligaments and muscles, a condition which often causes night-backache, because of which a patient awakes to find a more comfortable position. A backache appearing in the afternoon or evening is more frequently due to fatigue, poor posture or arthritis.

(As generalizations these statements are fairly sound, but it must be remembered that many cases of spondylitis are associated with paravertebral fibromyositis, symptoms of which may dominate at times, in which case the patient may feel worse on rising, better after some exercise—Ed.)

The "Newer Anatomy" of the Spine Until recently studies on spondylitis dealt almost exclusively with diseases of the vertebral bodies and adjacent ligaments. In atrophic spondylitis (spondylitis ankylopoietica) the chief pathologic finding was regarded as inflammation and calcification of paravertebral ligaments, the vertebral bodies not being affected early except by atrophy. In hypertrophic spondylitis (spondylitis osteoarthritica) tipping of vertebral bodies was evident. So, too, in suspected traumatic spondylitis roentgenographic evidences of trauma were sought in

vertebral bodies, if these appeared normal pain was ascribed to traumatized muscles and ligaments. However, since the work of Schmorl (1927 et seq), Schmorl and Junghanns (1932), Beadle (1931), Ghormley (1931 et seq), Keyes and Compere (1932-1933) and others, major interest has been transferred to the anatomy and pathology of the intervertebral disks and "paravertebral joints" or lateral "facets". Now it appears that a great number of cases of backache, (secondary) spondylitis and sciatica are due to diseases primarily not in the larger, more obvious, vertebral bodies but in the smaller structures—disks and facets. Thus current writers have given much space to discussions on the "newer anatomy and pathology" of these tissues. Since the work to which they refer in truth constituted "a new chapter on vertebral pathology," it seems well to review it here in some detail. (Since current writers freely referred to the reports of Schmorl and the others just mentioned, it was at times difficult to know when they were quoting and when they were presenting original observations. The following is a summary of data reviewed by them—Ed.)

One is likely to consider the spine as consisting of 24 vertebral bodies with their 23 intervertebral joints. As a matter of fact, according to Rechtman³⁹⁵ there are 134 joints in the spine between the skull and the sacrum, each vertebra having approximately 10 synovial-lined cavities. Furthermore, the 23 intervertebral "joints"—the spaces between the vertebral bodies—are not true joints at all, since they possess no synovial membrane but are made up of fibrocartilage—the intervertebral disks. These disks are composed of three main parts: the cartilage end-plates, the annulus fibrosus, and the nucleus pulposus. Each disk is bounded above and below by a vertebral body, the peripheral bony edges of which are slightly thickened anteriorly and laterally (but not posteriorly) to form the "epiphyseal ring".

The cartilage plates are thin layers of hyaline cartilage which form the top and bottom of the intervertebral disk and which fuse anteriorly and laterally with the bony edges or epiphyseal ring of the vertebrae to form the "rim ledge". The cartilage plates in turn enclose the "annulus lamellosus" or "annulus fibrosus," a dense fibrocartilaginous envelope composed of concentric folds of fibrous tissue. These folds form a strong elastic container for the nucleus pulposus, except toward the posterior edge of the disk (toward the spinal canal) where the fibers of the annulus are fewer and thinner.

The "heart" or "central lens" of the intervertebral disk is the nucleus pulposus, a fibroglutinous incompressible mass of tissue, partly cellular, partly fluid (88 per cent water at birth). Thus it is subject to the usual laws of fluids—it is under tension, and is capable of expansion but not of compression. The pressure of the nucleus pulposus after cutting away the annulus fibrosus is 18 mm of mercury. The pressure required to reduce its expansion is 32.2 pounds⁴⁰⁰. The position of the nucleus pulposus within the annulus fibrosus varies in different spinal segments, it is always rather more posterior than central but is farther forward in the upper thoracic region. The nucleus acts as a shock-absorber and diminishes the effect of

stress and strain on the spine, and at the same time it is the medium of transmitting pressure from one vertebra to the next. It is confined to its normal shape and position by the strong surrounding bands of the annulus fibrosus and it is on the integrity of the latter and of the cartilage plates that the normal function of the nucleus depends.

The simplest way to understand the intervertebral disk is perhaps to regard it as a rudimentary (but not a true) joint, the cartilage plates are comparable to articular cartilage, the annulus fibrosus to fibrous articular capsule, and the nucleus pulposus to a joint cavity (Malcolmson⁴⁰¹). The disks have the function, then, of being buffers and hydrostatic ball-bearings (Hadley⁴⁰²), and it is largely on the integrity of these disks that the normal function of the spine depends (Carpenter⁴⁰³). The disks in embryonic life have blood vessels,⁴⁰⁰ but the adult disk is thought to have no blood vessels. It gets its nutrition by diffusion of lymph through minute perforations in the bony surface of the spongy vertebral bodies. The disk has no nerves either, and since it has no nerves, the disk when diseased is *per se* painless. Pain is produced only when secondary changes occur in vertebral bodies and facets (Hart⁴⁰⁴). Since the disks have no blood supply they cannot become infected directly through the blood stream, however, they may be infected via lymph channels, and suppuration in the region of a disk may attack and destroy it^{405, 406}.

The only true joints of the spine are those which connect the superior and inferior (lateral) spinous processes. In the literature they are variously named "lateral intervertebral articulations" or joints,⁴⁰⁷ "intervertebral synovial joints,"⁴⁰⁸ "apophyseal articulations" or "posterior articulations of the spine,"⁴⁰² and "articular facets"⁴⁰⁹. They are true diarthrodial joints and possess joint cavities. Hyaline cartilage covers their surfaces, and they possess synovial membranes, articular capsules and articular ligaments. Hence they are subject to the same injuries and diseases that affect joints elsewhere.

The function of these joints is to permit motion in the spine and to act as stabilizers, but not to carry weight, which in a position of good posture they do not carry. Each joint permits only a fraction of an inch of motion, yet many of them together permit an appreciable amount. Leverage determines to a large degree the amount of force transmitted to the capsules of these joints, it being progressively less toward the head and progressively greater toward the sacrum, the greatest force being at the lumbosacral joint because the lateral intervertebral articulations are more or less in the sagittal plane, except at the lumbosacral joint where they are more obliquely situated. Therefore, at the lumbosacral joint an antero-posterior roentgenographic view does not show the joints in profile as it does in higher lumbar joints.

Ligaments and muscles usually prevent damage to the lateral intervertebral joints, even to those of the lumbosacral region, where the fifth lumbar body is normally inclined upon the first sacral at an angle of 40°. Here,

forward slipping is prevented by the inferior articular process of the fifth lumbar vertebra and by surrounding ligaments. The spinal nerves escape on each side by way of the spinal foramina, which vary in size as do the nerves. Unfortunately the smallest of the lumbar foramina is the fifth, through which the largest nerve trunk passes, and this has much to do with the great frequency of low-back pain involving the fifth nerve.¹⁰⁷

Pathologic Conditions Affecting the Intervertebral Disk, Results Thereof The parts of the intervertebral disks are so interdependent that disease of one part leads to disease of others. *Cartilage plates* may be affected variously. 1 Congenital defects, fissures or cracks, may weaken them and lead to prolapse of the nucleus pulposus. 2 Acute trauma may injure them and cause prompt escape of the nucleus pulposus. Roentgenograms will be negative for several months until thinning of the disks becomes apparent, until the nucleus, if it prolapsed into the spongiosum, becomes calcified, or until secondary osteo-arthritic changes become obvious. 3 Chronic trauma, particularly in the third and fourth decades of life, may injure the plate.⁴⁰³ Fibrillation from wear and tear in hard workers or in the aged, or even continued every day trauma, will cause minute cracks in the plates, with resultant dehydration, lessened resilience, thinning and destruction of the disk, excessive wear and tear on the margins of vertebral bodies, and subsequent osteo-arthritis (Schmorl). However, since Schmorl often found better preserved disks in the aged than in people of sedentary occupation, he concluded that the ordinary trauma of daily work plus individual constitutional factors, which vary greatly in different persons, plays a greater rôle than disease in producing degenerative changes in the disks. 4 Primary disease of cartilage plates is unknown or rare, but they may be secondarily invaded by diseases of the vertebral bodies, for example, tuberculosis and osteomyelitis.

The *nucleus pulposus* may be affected in several ways. 1 Retropulsion, or antepulsion, of the nucleus within the disk⁴⁰³ or prolapse of a nucleus into the spongiosum of an adjacent vertebral body may occur, chiefly from injuries producing tears in the annulus fibrosus, in cartilage plates, or both. Retropulsion of a nucleus into the spinal canal may occur and produce pain (with or without neurologic findings) and even paraplegia (Malcolmson,⁴⁰¹ Carpenter,⁴⁰³ Mixter and Ayer⁴¹⁰). Schmorl found some degrees of prolapse of nuclei in 38 per cent of 5,000 routine necropsies. If only a small portion of a nucleus is extruded, function of a disk may not be seriously impaired for a time, but dehydration and diminished function of a disk may later appear at an earlier age than otherwise. 2 Lateral shift of a nucleus to the convexity of the curve may occur, as in cases of sclerosis.⁴⁰¹ 3 Calcification of the nucleus may result from unknown causes, presumably from disturbances in calcium metabolism, trauma, senility, infection and so forth.⁴⁰³ Such deposits increase with age. They may appear in the nucleus or in the annulus, Ratheke (1932 cited by Joplin) found 6.5 per cent of

them in the nucleus, 71 per cent in the annulus. They appear in roentgenograms as branched shadows with several processes, projecting outward. They are generally in the central portion of the disk, but also in the periphery of the fibrous ring. 4 Dehydration occurs with advanced age. The water content of the nucleus at birth is 88 per cent, at 18 years 80 per cent, at 77 years 69 per cent. Thus progressive dehydration begins in the third and fourth decade⁴⁰⁰ and accompanies senility, but stress and strain hasten its development and it can be rapidly brought about by leakage of the nucleus from the several causes noted⁴⁰¹. 5 Infiltration of the nucleus by other tissue may occur, by bone or blood vessels, and especially by fibrous tissue replacement of old age or during health after trauma. 6 "Expansion" of nuclei sometimes occurs from release of pressure when adjacent vertebral bodies become softened from osteochondritis, osteitis fibrosa, senile osteoporosis, or neoplastic invasion. As a result of nuclear expansion, the disks appear spherical in roentgenograms, the vertebral bodies appear biconcave⁴⁰³. In extreme cases adjacent intervertebral disks may almost touch⁴⁰⁰, roentgenograms then show thick disks and thin biconcave vertebral bodies. Enlargement of disks in such cases was believed by Schmorl (1930) to be due to "expansion," by Moffett (1933) to result from compensatory hypertrophy.

Disturbances of *intervertebral disks* include (1) congenital absence of a disk,⁴⁰¹ (2) drying of tissue of the disk, (3) occurrence of fissures primarily in the disk, and (4) increased moisture in tissues of the disk, inducing gross fissure formation and ultimately destroying the disk. Infection of the disk via the blood stream presumably does not occur as the disk has no blood supply⁴⁰². (This is doubted by Bohmig⁴¹¹). However, suppuration adjacent to a disk may attack and destroy it. Changes in the disk become so frequent with advancing age that, after the middle of the sixth decade, it is almost impossible to find a spine in which all disks are normal⁴⁰⁵. Degeneration in the disk is characterized by a grinding up and drying out process with deposition of yellowish or brownish pigment of unknown composition. Large cavities are produced in the interior, but the outer periphery of the annulus fibrosus may remain intact⁴⁰⁰.

The eventual thinning and tendency to partial or complete destruction of the disks plays a large part in the production of several clinical syndromes: (1) hypertrophic (osteo-) arthritis of vertebral bodies and of facets, (2) radiculitis at various levels, (3) sciatica, (4) low back pain with or without sciatica, (5) occasional symptoms simulating those of cord tumor.

When Keyes and Compere (1933) punctured the annulus fibrosus of animals and allowed nuclear material to escape with prolapse of the nucleus into adjacent vertebral bodies, there ensued destruction of the disk, lipping of vertebrae, and osteo-arthritis. The same sequence of events occurs in man. Whenever thinning and destruction of disks occur, the vertebral bodies rub together, causing sclerosis, osteo-arthritis and lipping⁴⁰¹. As

noted, since disks contain no nerves, disease of disks is not painful per se until the development of vertebral or facet changes⁴⁰⁰. Some regard the vertebral osteophytes as evidence, not of arthritis, but of an attempt at stabilization, hence they prefer "spondylosis" to "spondylitis" (Beadle, 1931)

It is important from the medicolegal standpoint to realize that the radiologic diagnosis of disease of disks may have to be delayed several months after injury until secondary changes occur. Roentgenograms may not at once reveal all the damage from acute trauma, nuclear prolapse is not at once associated with visible roentgenographic changes. Conclusions must be drawn from the width of the intervertebral space and the condition of the borders of the adjacent vertebral bodies. Weakness of cartilage plates may be evidenced radiologically by the pressure of smooth excavations (unbuccination of disk material) into vertebral bodies (Malcolmson⁴⁰¹). When nuclear prolapse occurs, the first change is a fibrous tissue reaction. About a month later this is replaced by a rim of cartilage which becomes surrounded by a wall of sclerosed bone. The space becomes hollowed, and later (three or four months after injury), deposits of calcium in vertebral bodies become visible in roentgenograms. These Schmorl's knots⁴⁰¹ or nodules⁴⁰⁰ were previously thought to be enchondromas of the intervertebral disk (Mixer and Ayer⁴¹⁰).

Pathologic Conditions Affecting the Facets, Results Thereof The lateral intervertebral joints or "facets" may be affected (1) directly as the result of trauma, degeneration or disease, or (2) secondarily in connection with disease of the intervertebral disks and vertebral bodies. Occasionally a sudden forcible motion of the spine is too great or too quick for muscles to protect the capsule of the facet adequately. The capsule is strained, some of its fibers are ruptured, and local pain and muscle spasm are found, but roentgenograms do not show the synovitis of these joints or the swelling of its capsular ligaments⁴⁰⁷.

Rupture of a nucleus pulposus and narrowing of a disk will cause subluxation of the adjacent facet articulations. If enough fluid escapes so that the nucleus is destroyed, the disk thins and the vertebrae begin to settle, the axis of motion is shifted posteriorly to the articular facets, and the weight of the body is transferred to the lateral or anterior part of the vertebral bodies. Partial subluxation of articular facets and a diminution in the size of intervertebral foramina ensues (this is nicely shown in photographs by Hadley,⁴⁰² and in diagrams by Hart⁴⁰⁴). Local and referred pains are produced by tension on capsular ligaments, encroachment on the size of the lumen of the foramina, and impingement of the ends of the articular processes on the pedicle above and the lamina below (both of which are covered by periosteum). The over-riding and abnormal contact of the surfaces of the facets produce degeneration of cartilage, marginal hyperplasia and

exostoses which still further decrease the diameter of the foramen and lead to radiculitis^{402, 406}

Production of Low Backache and Secondary Sciatica When the series of events just noted occurs at the lumbosacral joint it is particularly productive of symptoms, commonly low backache and sciatica. The sciatic nerve is derived from the anterior divisions of the fourth and fifth lumbar and the first, second and third sacral nerves. The fifth lumbar nerve is, as has been said, the largest one but must traverse the smallest foramen. It lies between the lumbosacral intervertebral disk and the lumbosacral articular facets and may become involved in inflammation, either of the disk or facets. Sciatic radiculitis frequently results.

That the intervertebral foramina are "the crossroads of neuralgia" was borne out by the experience of Putti⁴¹² who noted "vertebral sciatica" in 231 of 345 cases of lumbar arthritis. According to Ghormley (1933) sciatica is more frequently caused by pressure on nerves or nerve sheaths at diseased facets than by disease of intervertebral disks.

Lumbosacral congenital anomalies, present in about 35 per cent of all persons⁴⁰¹ are frequent, some say the most frequent cause of sciatica or low back pain (O'Conner,⁴¹³ Bellerose⁴¹⁴). The fifth lumbar vertebra is in the process of developmental transition. In Wagner's⁴¹⁵ cases defects here produced pain involving or including the third lumbar to the third sacral segment, but most particularly the fifth lumbar and the first and second sacral segments of the spinal cord.

In occasional cases sciatica was found by Ayres⁴⁰⁶ and Mixter and Ayer⁴¹⁰ to be due to rupture of the intervertebral disk into the spinal canal. About 50 per cent of such ruptures implicate the fourth to fifth lumbar disks. 23 of their 34 cases, 42 of 81 collected cases. Usually fragments of both annulus and nucleus were present, hence "rupture of the disk" is a more correct term than "rupture of the nucleus". The herniated mass varied from 0.5 to 2 cm. in size. Trauma was the most frequent cause. Symptoms may not appear immediately thereafter. In lumbosacral herniation symptoms may be of sacro-iliac or low-back pain, of severe intermittent sciatica, or of caudal tumors. (Malcolmson⁴⁰¹ noted paraplegia in one case). Neurologic examination was sometimes negative. The protein content of spinal fluid was almost always increased (in 33 of 34 cases), even in spinal fluid from above the level of the hernia. Injections of lipiodol revealed partial subarachnoid block. Therefore, not even a tentative diagnosis of herniated disk should be made without finding increased protein in spinal fluid and a positive lipiodol test.

(Among a fairly large number of cases in which rupture of the disk into the spinal canal was proved at operation by neurosurgeons at The Mayo Clinic were several in which the protein content of the spinal fluid was normal. In only 20 per cent of the entire series was there roentgenographic evidence of thinning of intervertebral disks—Ed.)

Of additional interest are the following representative articles on low-back pain "commonly caused" by a tight iliotibial band ^{389, 416} and a description of the Ober method of treating the condition by sectioning the fascia lata, arguments for ⁴¹⁷ and against ⁴¹⁸ the idea that backache is frequently caused by sacro-iliac subluxation, backache from the urologic viewpoint ^{419, 420}, gynecologic conditions, such as displaced uterus or malfunctioning ovaries as a common ^{421, 422} or rare ^{397, 398} cause of backache, the diagnosis of destructive spinal lesions by "needle-biopsy" ⁴²³, and on manipulation in low-back pain from trauma and poor posture (Cox, ⁴²⁴ Wright ⁴¹⁷) A partial translation of Cotugno's *De ischia de nervosa commentarius* (1764) was given by Viets ⁴²⁵ with interesting historical comments

The Treatment of Low-Back Pain and Secondary Sciatica This is most variable and depends on the cause Hart ⁴⁰¹ and Hadley ⁴⁰² favored conservative treatment physiologic rest (on a firm bed, with or without extension, strapping, jackets, braces) and hyperemia by various physical means Roentgen therapy was distinctly helpful, Hadley stated When conservative therapy failed, spine fusion or facetectomy was advised Of 99 patients with "lumbosacral pathology" seen by Ayres, ⁴⁰⁶ 59 had thinned disks The results of Hibb's fusion operation, followed by the use of a jacket or brace, were successful in 80 cases, patients being well two to 10 years after operation Facetectomy was not necessary, and Ayres felt that if it were done with fusion the resultant mass of callus might involve the fifth lumbar nerve adversely

COMMON TYPES OF SPONDYLITIS

Excluding spondylitis due to frank trauma and specific infection, Kreuscher ³⁹¹ distinguished three types hypertrophic spondylitis, atrophic spondylitis, "which generally goes on to ankylosis," and nonspecific "infectious spondylitis," which is "often relieved by removal of infected foci" (The distinctions are not clarified further—Ed) Some regard spondylitis rhizomelique, or the Marie-Strumpell type, and the von Bechterew type as different diseases Spondylitis rhizomelique, spondylitis ankylopoietica, and the von Bechterew and Strumpell types are all regarded by Buckley ⁴²⁶ as the same disease, "ankylosing spondylitis," which, however, he considered distinct from, and not the spinal equivalent of, atrophic arthritis, because of the sharply-contrasting sex incidence and because, with ankylosing spondylitis, it is rare for more distal joints to be implicated Even when peripheral joints are affected therewith, "such cases may be distinguished from rheumatoid arthritis by the order of invasion, the spine and large joints preceding those of the extremities"

(The editors consider that some of these distinctions are relatively unimportant, that the von Bechterew and Strumpell types are probably varieties of atrophic spondylitis, and that the two great common types of spondylitis are atrophic spondylitis, the equivalent of atrophic arthritis elsewhere, and hypertrophic spondylitis, the spinal representative of hypertrophic arthritis as seen in peripheral joints—Ed)

Atrophic Spondylitis The relative incidence of atrophic spondylitis to atrophic arthritis was 1 13 in one series¹⁰³

Symptoms The usual symptoms were reviewed by several, for example by Buckley^{426, 427} who also summarized studies on the nervous manifestations of "vertebral rheumatism" Root pains and reflex changes may occur in both types of spondylitis In hypertrophic spondylitis, nerve symptoms are due to formation of exostoses, not from inflammatory exudates in atrophic spondylitis, however, they are rarely due to compression from exostoses or ossified ligaments but to inflammatory lesions of the epidural spaces or meninges Nerve pains are more frequent in the pre-ankylosing stage than when the spine is fixed, but girdle pains in the lower intercostal regions may be present after ankylosis has begun, probably from new bone deposits on the sides of the vertebral bodies In cases of brachial neuritis and minor nervous symptoms in arms, profile roentgenograms may reveal atrophy of the lower cervical vertebrae, with or without spondylitis, a point for further investigation⁴²⁷

Pathology This was described again bony ankylosis of vertebral bodies, not from osteophytes, but from calcification of vertebral ligaments, circumferential ossification of intervertebral disks, rarefaction and softening of vertebral bodies, and destruction and ankylosis of sacro-iliac joints⁴²⁶ (Also ankylosis of lateral intervertebral joints [facets], and costovertebral joints — Ed)

Roentgenograms These reveal a variable state, ossification being early in some cases, late in others Several noted early involvement of sacro-iliac joints (Buckley,⁴²⁶ Dawson¹⁰³), and Scott⁴²⁸ regarded it as of particular significance Of his 110 cases of "spondylitis adolescens," all showed bilateral infections of sacro-iliac joints with ankylosis According to him, sacro-iliac infection is long symptomless and generally starts several years prior to symptoms in the sacro-iliac joints themselves or in the back elsewhere Later, wandering pains about the shoulders, arms, ribs and legs may appear in all such cases roentgenograms of the (painless) sacro-iliac joints should be taken to detect the early stage of spondylitis—the sacro-iliac infection According to Scott, spinal symptoms do not begin until ankylosis of sacro-iliac joints has begun

Laboratory Data The plasma fibrinogen and total protein were higher in 12 cases of atrophic spondylitis than in cases of atrophic or hypertrophic arthritis (in other joints) seen by Aldred-Brown and Monroe²⁵⁷ Agglutinins to hemolytic streptococci are present in much lower amounts than in atrophic arthritis elsewhere (Dawson¹⁰³)

Etiology and Pathogenesis The cause of the disease is believed by the majority to be the same as that of atrophic arthritis (elsewhere) Buckley⁴²⁶ was in sympathy with Leri's idea that atrophic spondylitis is not a disease of joints primarily, but of bone, "an infectious or toxic osteopathy," and that the bacterium might be found in spongiosa In seven of 13 cases he noted increases in phosphoric esterase (phosphatase) of the blood, but he

considered this insufficient proof of a primary bone disease. Scott⁴²⁸ believed the primary cause of spondylitis to be the early sacro-iliac infection, which "in spite of meager evidence" may commonly be of tuberculous nature. Because it is so important to prevent the spread of the infection to vertebrae, Scott stressed the necessity of discovering the sacro-iliac infection early, before spinal or even sacro-iliac symptoms have arisen, by making roentgenograms of the sacro-iliac joints in all cases with "wandering pains" in the back.

(Our experiences confirm the observation of Scott that sacro-iliac changes are often present long before other roentgenographic alterations. Buckley, however, did not note sacro-iliac changes in every case. Further investigation is necessary before one can accept the pathogenesis of the disease as outlined by Scott—Ed.)

Treatment Scott further noted that to remove the sacro-iliac focus, "trephining and curetting of the sacro-iliac joints before the onset of ankylosis are being tried," also, irradiation of the spine and sacro-iliac joints by low doses of roentgen-rays of medium wave length. No results were given. Conventional treatment was advocated by most removal of foci, physiotherapy, belts, corsets or braces, and manipulation in selected cases^{390, 398}. Mecholyt iontophoresis was of no value (Abel³²⁰). The use of vaccine gave no relief (Sherwood³⁰⁹), though it made supervision of patients easier. Wilson^{355, 356} noted relief with short wave therapy.

Hypertrophic Spondylitis The synonyms are spondylitis osteoarthritica, spondylosis, spondylarthritis. To illustrate the new anatomic distinctions, Hawley⁴⁰⁹ used the term "spondylitis" referring to changes in vertebral bodies, and "arthritis of the spine" referring to "true spinal arthritis"—that of facet articulations. Thus also Shore,^{408, 420} in his studies on osteo-arthritis of the spine, preferred the term "polyspondylitis marginalis osteophytica" for (hypertrophic) osteo-arthritis of the vertebral bodies, anatomically a different disease from "osteo-arthritis of the dorsal intervertebral joints, the small synovial joints of the vertebral column."

Symptoms Current reports stress the nervous symptoms that may arise. Rosenberger⁴³⁰ attributed some cases of Horner's syndrome to (hypertrophic?) arthritis of the last cervical and first thoracic vertebrae. On certain movements of the head some patients noted neuralgic pains referable to the precordium or scapula, or spasm of the trapezius muscle. When symptoms arise from involvement of the upper three cervical vertebrae, occipital or suboccipital headache and pains in the neck may arise³⁸². Keefer³⁸² considered sensory changes common, but according to Rosenberger they are uncommon, as the involved nerves carry no sensory fibers to the skin. Each of three sisters, aged 67, 51 and 45 years, presented to Zabriskie, Hare and Masselink⁴³¹ a curiously similar syndrome of hypertrophic arthritis of the last four cervical (in the oldest patient, also of the thoracic and lumbar) vertebrae, subjective numbness and tingling of finger tips and atrophy of the thenar muscles of both hands. The atrophy was

believed due to direct pressure on spinal nerve roots at some point of their exit from the spinal canal. The onset of symptoms in these cases was between 44 and 49 years of age. No parallel syndrome was found in the literature. However, atrophy of thenar and hypothenar eminences was listed in Buckley's⁴²⁷ review of nerve manifestations of vertebral rheumatism, also noted were atrophy of other small muscles of the hand, atrophy of the Aran-Duchenne type, root atrophy of muscles (especially of leg and thigh), paresthesias, numbness and slight anesthesia, and sometimes muscle fibrillation and reflex changes. It was noted that osteophytes are sometimes seen at the vertebral level of root pain but on the side opposite the distribution of pain, indicating that it is not the formed osteophytes that produce pressure on nerve roots, but those in course of formation—ones as yet unossified and hence not visible in radiograms. (Bisgard, 1932, also described neurologic symptoms common in cervical arthritis—Ed.)

Pathology Hypertrophic spondylitis increases with advancing age³⁸². Certain vertebrae are affected much more frequently than others. In his study of 126 vertebral columns with osteo-arthritis Shore⁴²⁹ noted no involvement between the first and second cervical vertebral bodies, and very infrequent involvement between the eighth cervical and fourth thoracic levels. There were three marked "outcrops"—regions of most frequent osteophyte production: (1) the cervical outcrop, between the third and sixth (with peak between the fourth and fifth) cervical vertebrae, (2) the thoracic outcrop, increasing in frequency from the fourth to the ninth and tenth thoracic vertebrae, osteophytes then receding in frequency between the tenth thoracic and first lumbar vertebrae, and finally (3) the lumbar outcrop, most notable of all, with osteophytes most frequently between the third to fourth and fourth to fifth lumbar vertebrae. The three "minimum-points" were at the "anticlinal" vertebrae, which are supposedly balanced with a minimal tendency to slide or rotate and through which a plumbline would fall in the erect attitude of the body.

These curves of distribution of osteophytes from vertebral bodies were not quite the same as those found for osteo-arthritis of the small thoracic intervertebral joints⁴⁰⁸. In the latter, the four main outcrops were the cervical (whose peak was between the third and fourth cervical vertebrae, the cervico-thoracic peak at the cervico-thoracic joint), the thoracic (peak between the fourth and fifth thoracic vertebrae) and the lumbar (peak between the second and third lumbar vertebrae). Zones of minimal incidence were between the seventh, eighth and ninth thoracic and between the sixth and seventh cervical vertebrae.

Roentgenograms According to Scott⁴²⁸ sacro-iliac joints in "spondylitis osteo-arthritica" exhibit no pathologic changes roentgenographically, a sharp contrast to the constant changes in "spondylitis adolescens".

(This observation is at variance with general experience. Others, Zollner, 1930, Smith-Petersen, 1932—cited by Keefer,³⁸² noted anatomic changes in sacro-iliac joints increasing with age—Ed.) Several papers reproduced roentgenograms

of the pathologic changes in intervertebral disks which may lead to hypertrophic spondylitis ^{100, 101, 102, 110}

Etiology and Pathogenesis Varieties of trauma are considered the chief cause—occasionally acute trauma, more often chronic trauma of certain occupations, or of long-continued weight bearing resulting from man's erect posture ¹⁸² The distribution of osteophytes of the thoracic intervertebral joints was interpreted by Shore ^{108, 120} as follows: the cervical outcrop is probably due to weight bearing in the joints of the already dorsiflexed cervical vertebrae, the cervicothoracic outcrop results from the use of the upper limbs, by movements of dorsiflexion transferred from the limbs to the thoracic skeleton and by associated action of the erector spinae muscles, the thoracolumbar outcrop is the result of weight-bearing in the joints of the dorsiflexed lumbar column and absorption of the lower thoracic vertebrae into the lumbar curve as lordosis is established

Trauma alone, however, does not explain these changes satisfactorily, and trauma is but the last in a chain of circumstances which cause hypertrophic spondylitis. The series of events culminating in the excess trauma that stimulates osteophyte production is, as we have noted, now thought to include degeneration of intervertebral disks as the feature of primary pathologic importance

Treatment Accepting current ideas on pathogenesis it is difficult to see how removal of infected foci could help much, as it could not lessen trauma or restore the integrity of damaged tissue ¹⁰³ However, in spite of his conclusions on the general production of osteophytes by trauma, Shore believed some cases might be due to toxic or bacterial infection. In a case of severe "lumbago" with narrowed intervertebral disks and marginal osteophytes Shore isolated hemolytic colon bacilli (it is not stated from whence). Vaccine was prepared and given with "striking results." The patient was "cured" and subsequent roentgenograms showed that the intervertebral disks had recovered their proportions and osteophytes had "become static." (The case is mentioned without details—Ed.) Good posture must be adopted so that facets won't have to carry weight ¹⁰⁷ Heat, rest, massage, and supports were approved. When conservative therapy was inadequate, more radical therapy was advised: traction, casts, spine fusion or facetectomy. Operative and non-operative indications and methods were reviewed by Kreuscher ³⁹²

GOUT AND GOUTY ARTHRITIS

A reawakened interest in gout is apparent. For 15 years only about three articles on gout have appeared annually in medical literature written in English. Last year, however, there were eight or more. The writers insisted that gout is not uncommon. The experience of their patients indicated that nowadays a case of gouty arthritis is much more likely to be called "rheumatic fever," "infectious arthritis" or "acute arthritis" than to be diagnosed correctly. Gout is seen with increasing frequency by those

on the alert for it. In England, three of every 1,000 insured workers become disabled thereby (Glover, 1924). Of workers at "hot occupations," (e.g. stokers) admitted to Buckley's clinic for rheumatism, 8 per cent had gout. He suggested that excess loss of perspiration altered the saline content of tissues and the solubility of sodium bi-urate.

Clinical features of classic gouty arthritis were reviewed by Gupta,⁴³² Cohen,⁴³³ Fitz,²⁶⁵ Hench,^{49, 106} Lockie and Hubbard,⁴¹¹ Monroe,⁴³⁵ Talbott, Jacobson and Oberg,¹³⁶ Volini and O'Brien.⁴³⁷ Among features stressed were these. Gout may affect the poor, the vegetarians and teetotalers as well as the rich, the meat eaters and the alcoholics.^{432, 431} Gout rarely affects females. 98 per cent of patients are males.^{49, 106} However, four women with gout were noted by Monroe and by Talbott et al. The age at onset of gouty arthritis is generally after 40 years, however, in 28 per cent of Monroe's cases it was under 30 years. The onset was at the age of 10 years in one of his cases and at 12 or earlier in the case of another.⁴³⁶ The first attack is likely to be in a large toe (in 74 per cent of one group⁴³⁵) but often a knee, ankle or other joint is affected and the great toe may long be spared. When the great toe is affected maximal tenderness is generally at its mesial surface.¹⁰⁶ A later, or even the first, attack may be polyarticular, with some tendency to migration. In spite of much pain and localized redness, attacks are often without fever or leukocytosis. Spine, hips and jaws which are rarely affected, were involved in some cases.^{435, 436} Since olecranon bursitis occurs at least five times oftener in gout than in atrophic arthritis, its presence should suggest gout.^{106, 437} The blood uric acid almost always becomes elevated, although not in some cases until late in the disease. It is occasionally normal even in a patient with tophi (Monroe⁴³⁵). It often returns to normal under adequate treatment but may remain elevated even though gouty arthritis is controlled (Cohen⁴³³). At a given time tophi are found in only 50 to 69 per cent of cases.^{106, 435} They are easily and repeatedly overlooked until sought by one suspecting gout. A "tophus" is not a tophus no matter where it is located until it is opened and found to contain urates. Roentgenograms are generally of little value in early diagnosis, generally become "characteristic" only late in the disease. Attacks of acute gouty arthritis subside "rapidly or grudgingly."⁴³⁵ Between early attacks complete functional restitution of joints practically always occurs. However, a few (12 per cent) of Monroe's patients were not entirely free of pain between acute exacerbations. When the acute attack is over, chronic symptomless gout still persists and must be treated.^{49, 106, 437} "Proven gout" from the pathologic standpoint means tophaceous gout, but a diagnosis of "presumptive gout" (provable from the clinical standpoint) must be entertained in all patients without tophi who exhibit the characteristic pattern of gouty arthritis—early acute attacks (in one or more joints, with or without hyperuricemia) with complete remissions, later, of chronic gouty arthritis.^{49, 106}

(Monroe's case 4, that of a male, is of special interest. The first attack at the age of 32 years involved hips and then knees, feet and many other joints including the jaws. After four months, recovery was "fairly complete." The diagnosis was rheumatic fever. Subsequently less severe attacks repeatedly involved practically all joints including the spine. Physical examination, at the age of 57, revealed tophi, hyperuricemia, swollen temporomandibular joints, fingers and ankles, and stiffened wrists, elbows, hips and knees. Roentgenograms of hands and feet showed "marked hypertrophic changes." In the absence of rheumatic carditis and with tophi ultimately present, Monroe concluded the first attack was also probably gout. Four months is very long for an initial arthritis of gout or of rheumatic fever. If all of this patient's attacks were of gouty arthritis, the involvement of jaws, hips, and spine makes it worthy of special note as we are unaware of any proved cases of gout in these joints in the literature of the past many years—Ed.)

The report of Gupta is also of special interest. He had records of 250 cases of gout and noted "the existence of 700 to 800 untreated cases of gout" in Nepal, India, which has a population of 40,000 to 50,000—an admittedly astonishing incidence of 60 to 70 cases of gout per 1,000 population. This was all the more unusual since great numbers of the natives, including many with gout, were absolute vegetarians and teetotalers because of great poverty or their religion. Six cases were detailed.

(Comment thereon is in order. Four of the six patients reputedly had "tophi," the authenticity of which would have been unquestioned had photographs of them or their contents been shown. It was not specifically stated that they were opened and examined. However, we are inclined to accept them as tophi since a characteristic history of gout was present in three of the four cases. One patient had "chalky concretions on ears and eyelids," and an eight-year-old boy who had had repeated acute podagra and "whose family had gout" presented tophi on ears and in nasal cartilages. Tophi on eyelids and in the nose have been reported, but they are most uncommon even in severe, chronic gout. Therefore, without more data one is skeptical. Patient 2 had acute attacks in great toes and knees with sciatica, his "mother, two brothers and a sister were gouty." Case 3 was that of a man without arthritis, whose radial neuralgia was considered gouty because of hyperuricemia and because atophan gave prompt relief after morphine and other drugs failed. Case 4 concerned a woman with a blood uric acid of 4.5 mg per 100 c c, "tophi," and a history of pain in her great toes. She had hypertension, interstitial nephritis and a recurrent bleeding tonsillar abrasion. A diagnosis of retrocedent gout was made since the "usual measures for gout" reduced blood pressure and stopped hemorrhages. The patient may have had gouty arthritis, but the diagnosis of retrocedent gout is debatable—Ed.)

Bassler⁴³⁸ reported gastrointestinal symptoms in 23 cases with "chronic and irregular forms" of gout. The symptoms were believed due to or associated with gout and included pyrosis, eructations, flatulence, constipation, heaviness and drowsiness after meals, abdominal and pelvic pain, colonic distress, colics and cramps, excess mucus in stools, nausea and anorexia. From these alone the diagnosis of gout cannot be made, it must be made on the condition of joints and the blood uric acid. "In gout the total uric acid per 100 c c of blood and urine combined is always above high normal.

Studies were made on 10 patients as to the uric acid and urea ratio using

1 to 55 as the standard and also on the alkalinity of the blood " (No figures or results are given to explain these statements—Ed) "The suggestion of the disorder comes from deposits of urates causing stiffness in the ligaments and are noticed (sic) in the feet and slightly less so in the hands" Bassler gave colonic instillations of oxygen for the intestinal toxemia of a "distinctly gouty woman" Within two weeks she was relieved of "night leg cramps, stiffness of knees and fingers improved markedly and she could flex the tips of her fingers to the palms for the first time in four years" Thereafter he treated with oxygen 22 cases of what he considered digestive manifestations of gout "In all but five cases a strikingly quick result on the symptoms took place"

(No data of any sort are given concerning the history, sex, physical examinations, blood uric acid concentrations, presence of tophi, roentgenograms of joints or laboratory tests on intestines It is impossible for us to conclude from the data given how many, if any, of the cases were of gout, and that the intestinal symptoms were relative thereto In the case of the woman just mentioned, no proof is given that she had gouty arthritis and not chronic non-gouty arthritis No figures are given to support the statement that oxygen instillations reduced the uric acid content of blood and urine—Ed)

One of Monroe's ⁴³⁵ patients regarded an attack of diarrhea and malaise as a regular warning that gouty arthralgia was soon to follow Another of his patients on a regimen for gout got relief from gouty arthritis but not from persistent salivation and hawking, for which a diagnosis of 'gouty bronchitis' had been suggested The incidence of vascular disease was definitely higher in his gouty than in his other patients with atrophic or hypertrophic arthritis Although there was a basis for argument, Monroe concluded that "irregular gout" was a highly speculative affair, evidence for which was usually most inadequate Volini and O'Brien ⁴³⁷ also concluded that the dyspeptic symptoms which Lichtwitz (1934) and others regarded as precursors of acute gout "are so much more frequently associated with gastrointestinal and gall-bladder disorders that they seem of little value as a warning sign"

(As one writer said, only one in four patients with gout receives a correct diagnosis, but it is also true that in some quarters only about one in four patients who receive a diagnosis of gout actually has the disease Slocumb,⁹⁹ for example, found several European physicians making a diagnosis of gout in cases of Heberden's nodes, or of transitory, mild subdeltoid bursitis, or in certain cases of chronic arthritis with "gouty dyspepsia" without tophi, hyperuricemia, or history of recurrent acute attacks and remissions One distinguished physician with a wide knowledge of classical gout expressed his feeling that solitary chronic arthritis of the second or third metacarpophalangeal joints of women or men was practically always gout even without hyperuricemia, tophi, or recurrent acute attacks the only basis for the idea was admittedly his "clinical experience" It has been said that the accuracy of a physician's criteria for gout can be judged on the number of his patients who have tophi or are females If more than 50 to 70 per cent of his patients have tophi he is too exclusive and is probably omitting cases of bona fide (even if pretophaceous) gout

If less than 35 to 40 per cent have tophi or if more than 2 to 5 per cent are females he is too inclusive diagnosing gout where it does not exist. Because tophiaceous or even pretophiaceous gout in females is very rare, it should be noted that the father of Fitz' ²⁶ patient, also two brothers and a sister, had gout and "one of his daughters has a persistently elevated blood uric acid though she has never had true podagra." One of Gupta's six patients was a woman, and the mother, two brothers and sister of another patient were also "gouty." One of Bassler's patients was a "distinctly gouty woman." Only four of Monroe's 59 patients were females. One was reported as having a "degenerating tophus." Further investigation ²¹² led Monroe to conclude that the nodule was not a probable tophus, and that although the history was very suggestive of gout, the very low level of blood uric acid and the unsettled matter of the 'tophus' made the diagnosis uncertain. All of which leads us to conclude that it is not always easy to decide when "gout" is truly gout, that the diagnosis of gout in females must be made with extra caution, and that, when it is made, full details in support thereof should be given—Ed.)

Agents Which Provolve Gouty Arthritis It is of diagnostic importance to remember that acute gouty arthritis frequently appears with changes of seasons (spring and fall), after gastronomic or alcoholic celebrations, after fixed festivals such as birthdays, Thanksgiving, Christmas or the Passover, after acute or even trivial trauma such as a day's automobile driving and while patients are receiving certain types of treatment such as salyrgan or other strong diuretics for cardiac decompensation, liver extract for pernicious anemia, ergotamine tartrate (gynergen) for migraine or for the pruritus of icterus, and, very rarely, after insulin (Hench ^{49, 100}). Hench noted that gouty arthritis was frequently provoked by activities incident to a hunting or fishing trip (tight boots, rough walking, damp and excesses in meat and alcohol). As a result some of his patients "had to be carried home—game, gun and gout."

Leukemia and polycythemia are not infrequently complicated by acute gout, as was lead poisoning formerly. Krafka ⁴³⁰ noted that any (hemolytic or hematonic) condition which tends to stimulate the erythropoietic system may provoke acute gout. Lead is an active hemolytic agent and every low blood count is compensated for by an increased marrow activity. Hemorrhages, "bleeding," and liver extract are marked hematopoietic stimulants. Bone marrow is stimulated, and an increase in erythrocytes results. Endogenous uric acid rises from the destruction of the extruded nuclei of the normoblasts in the maturation of erythrocytes. Acute gout ensues.

In line with the observation of others that starvation or high fat diets induce marked increases in blood uric acid concentration, Lockie and Hubbard ⁴³⁴ found that the administration of a high-fat, low-carbohydrate diet (fat 250 to 350, carbohydrates 30 to 50, protein 50 gm) for five to seven days promptly provoked acute gouty arthritis in four cases but did not affect patients with non-gouty arthritis. In some cases blood uric acid rose markedly and the urinary uric acid content fell, but the symptoms provoked were not directly dependent on the altered blood uric acid. The induced attacks were promptly relieved by diets high in carbohydrates, low

in fat The provocative diet was therefore proposed as a diagnostic test and it was concluded that diets high in fat and low in carbohydrates should be avoided for patients with gout The wisdom of this advice was confirmed by Hench¹⁰⁶ who noted the development of acute gout in several patients whose bacilluria was being treated by the ketogenic diet

(The diets of Lockie and Hubbard were not ketogenic as it is almost impossible to produce ketosis with a carbohydrate intake of more than 15 to 20 gm It should be determined to what extent ketosis must be approached to provoke gout—Ed)

Within 12 to 120 hours after almost any surgical operation patients with quiescent (unsuspected) or active gout are prone to develop acute gouty arthritis Coburn and Pauli¹⁷⁸ noted that surgical operations occasionally provoked a recurrence of rheumatic fever Hench^{49 106} found, however that the great majority of about 50 cases of acute postoperative arthritis were ones of acute gouty arthritis and approved the axiom "In cases of acute postoperative arthritis (especially in males over 40 years of age) suspect gout" Clinical and chemical details of two such cases were given (The provocative effect of surgical operations in gout is in striking contrast to the temporary benefit that almost any surgical operation may provide for patients with atrophic arthritis—Ed)

Laboratory Data Two of Miller's²⁹¹ six patients had some degree of hepatic inefficiency as shown by levulose tolerance tests Blood proteins in three cases of gout were as follows albumin 4.0 to 4.4, average 4.2, globulin 2.2 to 3, average 2.5, total proteins 6.9 to 7.3, average 7.1 gm per 100 cc²⁸⁷ (In neither of these reports did it state whether tests were done during active gouty arthritis or quiescent gout—Ed) Roentgenograms in gout may not be characteristic and frequently simulate those in chronic non-gouty arthritis (Doub¹¹)

Pathology Galantha⁴⁴⁰ described a new technic for the preservation and microscopic demonstration of urates in gouty tissues The crystals therein were beautifully demonstrated (Formalin dissolves urates promptly and gouty tissues fixed therewith will show no crystals, merely crystal clefts Galantha's method uses absolute alcohol as a fixative—Ed)

Etiology and Pathogenesis It is now commonly believed that an excess of urates alone is not the cause of gout but merely an index of the metabolic disturbance that causes it As Ray³⁵¹ stated, the etiology of gout is very obscure and estimations of blood uric acid are of satisfaction only to those who still believe purine bodies are causes of gout Observations supporting the idea that gout may be a more widespread disturbance of bodily equilibrium than a dysfunction of uric acid metabolism were made by Talbott, Jacobson and Oberg⁴³⁶ who studied the electrolyte balance of two gouty patients In one case 50 attacks were studied in 22 months, in another seven attacks in nine weeks Changes in water and salt metabolism were as follows diuresis began before any clinical or subjective evidence of gout was manifest A negative sodium and chloride balance accompanied this diuresis and there was also an increased excretion of potassium, calcium, am-

monium, titratable acid, phosphate and urate. The previous observation of others that prior to an attack there is a decrease in urinary uric acid, was not confirmed.

(Statistical data presented deserve full consideration and may suggest new treatments. Those who have made metabolic studies, particularly on patients with gout who consider themselves "well" when the acute arthritis is over, will agree that the authors need make no apologies for having presented studies on only two cases, for the studies were very carefully made over long periods. Because of the continual shifts in electrolytes, the authors considered it doubtful whether a period of normal fluid and electrolyte balance of significant duration is ever observed in patients with gout. However in these two cases the frequency of attacks was so great [averaging an attack in one case every 13 days, in the other every nine days] that one might regard these patients as having, not acute recurrent gouty arthritis but chronic gouty arthritis with acute exacerbations. Studies should be made on patients with earlier, less active gout to see whether they demonstrate long periods with a normal equilibrium. The second patient was a woman. While the published report does not state that she had tophi, we are informed that she had numerous tophi and, a few days after thyroidectomy, severe, postoperative, acute gouty arthritis²¹²—Ed.)

Habitual use of alcohol was admitted by 62 per cent of Monroe's patients. That gout may affect vegetarians and abstainers from alcohol indicates that excesses of food and drink are probably only precipitating factors, not the cause of gout. The majority discount the factor of infection except as a provocative, but some (Gupta,⁴³² Willcox⁴⁴¹) favor the infectious theory. Llewellyn's theory that gout is an allergic manifestation to specific proteins was attractive to Nisse⁴⁴². "a focus of infection is likely to produce repeated attacks of gout by sensitizing a joint, already handicapped by a defective purin metabolism, to the effects of the bacterial antigen produced by the focus." A reverse sequence was suggested by Willcox⁴⁴¹. "in gout there is often some chronic infection which has sensitized the body and which has caused the uric acid metabolism to be disturbed."

Treatment The diet proposed for treatment by Lockie and Hubbard⁴³⁴ contained 350 to 400 gm of carbohydrate, 50 gm of protein, and no more than 50 gm of fat. Attacks of acute gout were relieved thereby. Pisanì⁴⁴³ independently noted the benefits of a high-carbohydrate intake in gout and administered glucose orally, rectally, or intravenously, depending on whether gout was active or quiescent. Joltrain⁴⁴⁴ gave his patients skin tests with purine and non-purine containing foods and interdicted all foods to which the patient's skin reacted, as well as many purine-containing foods. Diet in gout is a matter of quantity rather than quality, according to Watson⁴⁴⁵ who regarded the use of small amounts of presumably dangerous foods as harmless. The diet should be purine-free for three to four weeks after an attack, then it should be low in purine but high in non-purine containing proteins (milk, eggs, cheese)^{49, 106, 433, 437}. A common mistake is to stop treatment as unnecessary once the acute attack is over. Interval treatment is essential to prevent not only the otherwise almost inevitable return of

gouty arthritis, but to control the potentially fatal effects of gout on the cardiovascular and renal system. Therefore, such a diet should be continued indefinitely. For this reason also some advise the intermittent use of cinchophen (three consecutive days each week) long after the acute attack is over. Although the routine use of cinchophen provides some risk to the gouty patient, it is, according to Hench,^{49 106} a minor and justifiable risk which must be taken whenever gout cannot be controlled by diet alone (which is very often the case). The mathematical chances of gouty patients being seriously or even fatally affected with gouty nephritis, renal stones, apoplexy or coronary disease (the not uncommon complications of gout), although moderate, present a more real danger than the rather remote chance of a significant toxic effect from cinchophen. Cinchophen and neo-cinchophen were used by Volini and O'Brien but, when contraindicated, were avoided in favor of salicylates and glycine, the synergistic action of which reputedly increases urate excretion (Quick, 1933). Cinchophen was avoided by Cohen⁴³³ in favor of colchicine given in small doses every fourth week between attacks.

Acute postoperative gout can generally be prevented, according to Hench⁴⁹ by the following regimen: for five to six days before and after operation the patient is given a purine-free, high carbohydrate diet, a generous intake of fluid, $7\frac{1}{2}$ grams (0.48 gm.) of cinchophen, t.i.d., and enough sodium bicarbonate to alkalinize the urine constantly. If a patient with gout must have liver extract for an associated blood dyscrasia, the experience of Fitz'²⁹⁵ patient should be recalled. He took orally four ampules of Lilly's liver extract No. 343 daily for three months without precipitating acute gout. Tired of eating liver, he was given one intramuscular injection, which was followed immediately by the worst attack of gout he ever had. Fitz quoted Minot to the effect that such provocation is rare. Another gouty patient with anemia had recently taken intramuscular injections of liver extract for several months without the development of acute gout or increased hyperuricemia.

A review⁴⁸ of results of fever therapy included the following: Berris' (1933) patient with chronic gout of three years' duration, who was unrelied by various measures and was unable to walk for four months, obtained "complete relief" after six fever sessions, being able to walk without pain after the second session. Auclair was also credited with good results in the treatment of gout, but no details were given. Slot⁴² found gold valueless in gout. A mixture of goose-grease, pig-fat, sheep-tallow and pitch "alleviates the gout in anyone. This goose-fat is worth more than any treasure," according to an amusing verse translated by Brooke⁴⁴⁶ from a Seventeenth Century manuscript.

Cinchophen Poisoning This was not reported in cases of gout last year. However, four patients with other diseases developed it. A woman with atrophic arthritis had "subacute yellow atrophy" after taking 30 tablets of

oxyiodide in 25 days. A Talma-Morrison operation was done, at which time the condition of the liver was apparent, the patient recovered (Clarke and Settle⁴¹⁷). A young woman whose primary disease was unstated, died several weeks after developing jaundice, the result of taking 30 tablets of Cinsa-Vess (5 grains, 0.3 gm, cinchophen, 1/200 grain, 0.0003 gm, colchicine per tablet) (Peluse⁴¹⁸). A young woman with rheumatic fever died with acute yellow atrophy after taking 37½ grains (2.48 gm) of cinchophen in five days (Fraser⁴¹⁹). A man, aged 52 years, became jaundiced and died after taking for three months "a patent medicine containing cinchophen", at necropsy hepatic cirrhosis but no central necrosis was seen. Isolated from the patient's urine was normal coproporphyrin, increased in amount because of damaged excretory power of the liver. This is considered the first report of the isolation of a porphyrin from the urine of a patient suffering from jaundice or hepatic disease (Watson⁴²⁰). Cases of acute yellow atrophy, some fatal, due to the use of "M S T" (Martin's specialized treatment) began to accumulate, it and two other patent nostrums, Morton's No 1 and No 2 (containing cinchophen or neocinchophen) were barred from the U S mails⁴²⁰. Gastric and duodenal ulcers have previously been produced in dogs by administering cinchophen. Schwartz and Simonds⁴²¹ found cats very susceptible, guinea-pigs moderately resistant, and rabbits very resistant, to massive doses of cinchophen, four of six cats but none of the other animals developed gastric ulcers. The undoubted production in humans of gastric or duodenal ulcers by cinchophen has not been noted clinically or at necropsy.

The Uric-Acid Problem According to Beer⁴²² many (non-gouty) patients with highly acid urine develop symptoms of renal or ureteral colic with microscopic or gross hematuria from showers of uric-acid crystals, gravel or stones. Uric-acid gravel is a conglomeration of uric-acid crystals, the "stones" are rarely larger than "half the size of a pin-head". Passage of gravel produces the same symptoms as those occurring with the passage of sizeable calculi. Urate stones and gravel are invisible in roentgenograms. The similarity to calculus disease in the presence of "negative roentgenograms" has caused confusion and wrong diagnoses of nephralgia, sympathetic nerve disturbances of kidney or ureter, and stricture or kinks of the ureter. In Beer's cases uric acid in the blood was not increased. After a shower of gravel, one may see with a cystoscope minute calculi on the vesical floor or protruding from swollen, traumatized ureteral meatuses. Uric acid crystals redissolve in the bladder, gravel does not, after a shower of crystals, they can be seen in the bladder only rarely, but if a fresh specimen of urine is preserved three to four days in a sterile test-tube, the crystals become apparent as typical "brick-dust". Generally the treatment in such cases is reduction of protein, increase of vegetables, fruits and water in diet, and the use of alkalis. In three of Beer's cases colic, ureteral obstruction, anuria and severe constitutional symptoms developed, and were relieved only by cysto-

scopy and ureteral catheterization. In one case showers of crystals were actually seen shooting from a ureter.

(These patients presumably had neither gout nor the "gouty diathesis," but apropos of the tendency of acute gout to develop within the first six postoperative days, it is interesting to note that in Beer's first case colic, hematuria and ureteral obstruction occurred "about the fifth operative day" after appendectomy. One of us (P. S. H.) has observed "ureteral flash-colics" without other urologic symptoms in a few cases of gout and has collected brick-red uric-acid gravel. This recalls the pamphlets of an earlier century "On the gravel and the gout"—Ed.)

Normal values for uric acid in the blood were redetermined with the revised micro-Folin method (1933) by Berglund and Frisk.⁴⁵³ The mean uric acid value for unlaked blood was 2.7 ± 0.07 mg per 100 cc for 89 normal women, 3.2 ± 0.08 mg for 43 normal men. These workers noted the effects of salyrgan, novatophan, euphyllin, caffeine, pituitrin and lithium urate on uric acid elimination in man. With normal or damaged kidneys they found a linear relationship between uric acid in blood and urine, the elimination index. Salyrgan increased uric acid excretion, not by altering the mode of urate elimination, but possibly by altering the state in which uric acid exists in blood. (Salyrgan influences plasma colloids—Ed.) The effect of novatophan was somewhat similar, there was no correlation between dosage and effect on uric acid elimination. Euphyllin also augmented uric acid excretion. Caffeine produced no significant changes in blood uric acid or glomerular filtration. The effect of pituitrin was difficult to interpret: there was halving of the elimination index but changes in blood uric acid and in the glomerular filtration rate seemed insignificant. In light of these experiments the authors discussed the rôle of glomeruli and tubules in the secretion of uric acid and presented data to show that the concentration of uric acid by the kidney can be greater than that of blood.

Quick⁴⁵⁴ found that after strenuous, but not after mild, exercise the excretion of uric acid, but not of creatinine, was markedly diminished, uric acid and lactic acid in the blood rose slightly but definitely. He concluded that the diminution of uric acid excretion was due to excess production of lactic acid. Since neither lactic acid nor strenuous exercise apparently affect renal function, the uric acid retention is somehow linked with the metabolism of lactic acid, with which liver is concerned. Hyperuricemia in eclampsia, chloroform poisoning, cardiac failure and pneumonia result from the increased blood lactic acid that occurs in these diseases. (This report suggests that patients with quiescent gout might provoke an attack by strenuous exercise—Ed.)

Cinchophen presumably mobilizes uric acid in human tissues and increases urinary uric acid 70 to 330 per cent. The administration of cinchophen generally causes (partial) evacuation of tissue-urates in about two to three days, after which additional doses do not augment uric acid excretion further. Furth and Edel⁴⁵⁵ attempted to discover whether the use of sufficient doses of phenyl cinchoninic drugs would completely evacuate rat's livers of their uric acid content. On the diet used the normal uric acid content of

rat's liver was rather constant, about 6.5 ± 1 mg per cent. On administering cinchophen and tolysin there was an equal and marked reduction, not a complete evacuation, of hepatic uric acid to an irreducible minimum of about 1.5 mg per cent. Although a maximal effect was obtained by about 0.01 gm of the drugs daily per kg of body weight, noticeable effects were obtained by 0.008 gm per kg daily (corresponding to a dose for man of only one-tenth of a single dose of 0.5 gm, $7\frac{1}{2}$ grains).

Although the excretory effect of cinchophen and tolysin was the same, the former was much more toxic to rats, as determined by a much greater loss of body weight.

(These experiments suggest that cinchophen and tolysin may be clinically effective in much smaller doses than now used—Ed.)

Of interest also are the studies of Matsuomoto⁴⁵⁶ regarding the effect of mechanical and chemical damage to kidneys on the excretion of uric acid by the liver (into bile) of rabbits. In general, there was an augmented, possibly compensatory, excretion of uric acid in bile.

In rats, Borsook and Jeffreys⁴⁵⁷ found that purines are converted into uric acid chiefly by liver and intestinal mucosa. Both these tissues actively convert guanine, xanthine and hypoxanthine. Mucosa alone converts adenine to any extent. Kidney and spleen have only a moderate, and striated muscle very little, effect on these purines.

PSORIATIC ARTHRITIS ARTHROPATHIA PSORIATICA

Two views exist regarding psoriatic arthritis: that it is a special entity, or that it is ordinary atrophic arthritis in a person who also happens to have psoriasis. Psoriasis may of course occur quite independently of a coexisting affection of joints and be only casually associated with any kind of arthritis. Thus it is not uncommon to see patients with atrophic or hypertrophic arthritis, or even rheumatic fever, with an entirely unrelated psoriasis. Because these incidental associations have erroneously been described by some as psoriatic arthritis, the existence of a true syndrome of psoriatic arthritis has been vigorously denied by many and the issue clouded. Certain features of psoriatic arthritis are quite distinct, one feature is practically pathognomonic according to Hench¹⁰⁶. Except in one anatomic situation, the appearance of psoriatic arthritis is quite like that of mild or moderately-advanced, only occasionally severe, atrophic arthritis, and is indistinguishable from it objectively or roentgenographically. In one regard, at least, psoriatic arthritis is rather unique. It may involve knees, ankles, feet, elbows, wrists and hands, but it has a special tendency to involve the terminal joints of fingers and toes, with or without involvement of other joints of fingers and toes. Furthermore, the nails adjacent to affected, terminal phalangeal joints of fingers and toes practically always exhibit definite psoriatic changes. These differentiating points are illustrated in photographs (Hench¹⁰⁶). Terminal joints of fingers and toes are

rarely involved in atrophic arthritis, as a rule only in the most severe cases and then only late. Terminal joints of fingers in hypertrophic arthritis are of course commonly affected with Heberden's nodes, but the terminal joints of toes are strangely exempt. Of diagnostic value, then, is the distinction that, in psoriatic arthritis, terminal joints of fingers and toes are commonly involved early in the disease, with psoriasis of adjacent nails. When these joints are not (yet) involved, psoriatic arthritis in other joints must be diagnosed by other features.

Psoriatic arthritis rarely comes with the first or with a mild bout of psoriasis. It usually attends a later or severe bout, when the patient has become careless in treating the skin lesion. In early phases of mild psoriatic arthritis a parallelism exists to some extent between the lesions of skin and those of the joints—when the skin is worse, arthritis appears, when the skin clears up spontaneously or under treatment, arthritis may diminish or disappear, even when the skin alone is treated. In severe or recurrent psoriatic arthritis articular symptoms may persist, the arthritis adopts its own rhythm and may be only partly relieved by measures for the skin.

Boots³¹ did not recognize psoriatic arthritis as an entity, it is not included in his classification and he stated: “(in rheumatoid arthritis) psoriasis is not uncommon and has been referred to as psoriasis arthropathica.” His colleague, Dawson,¹⁰³ took a more equivocal stand. Although he did not classify it or separate it definitely he stated, “the association of psoriasis in rheumatoid arthritis cannot be regarded as a mere coincidence.”

(In the early stages of psoriatic arthritis, joints may sometimes recover function and the articular disease become inactive to a degree and with a speed not expected in atrophic arthritis. Boots and Dawson both showed photographs of the same young girl. Boots labelled it “Rheumatoid arthritis in a child [Still's disease]. Note fusiform fingers and psoriasis.” Dawson labelled it “Psoriasis arthropathica.” The condition of the terminal joints is not well seen in the photographs, so that the reader cannot venture an opinion on which form she may have had, but it may have been psoriatic arthritis as it is noted that she recovered to an unusual extent—Ed.)

The main treatment for psoriatic arthritis is control of the psoriasis, with such additional routine measures for joints as are necessary. Hench favored Goeckerman's (1925, 1931) treatment of the skin: applications of White's crude coal-tar ointment and ultraviolet (quartz) irradiation.

Several general articles are noted, though they did not mention psoriatic arthritis: one on psoriasis as a possible allergic manifestation,⁴⁷⁸ and a review of the modern treatment of psoriasis.⁴⁵⁹ Sperry⁴⁶⁰ used large doses of theelin intramuscularly in repeated courses to control but not cure severe psoriasis. Elson⁴⁶¹ considered psoriasis an enzyme deficiency disease: “Massive doses of pancreas extract will cure psoriasis.” Two of Schwartz' patients⁴⁶² were benefited by the intramuscular use of colloidal manganese. According to Thurmon⁴⁶³ “the more severe or extensive the psoriasis the more gratifying is the result obtained with intravenous organic sulphur.”

HEMOPHILIC ARTHRITIS

Hemophilic arthritis may occur with each of three types of hemophilia (1) true hereditary hemophilia, in which the bleeding tendency is a recessive sex-linked characteristic appearing only in males and transmitted only by females, (2) hereditary pseudohemophilia, in which the bleeding tendency is a dominant sex-linked characteristic and an affected mother or father may beget affected children of either sex and (3) sporadic or spontaneous hemophilia, cases of apparently true hemophilia in which no hereditary bleeding tendency can be proved. Three patients with hereditary pseudohemophilia, two sisters and the son of one, all with recurrent hemarthrosis, were seen by Handley and Nussbrecher.⁴⁶⁴ Family records, clinical and laboratory data, and the genetic relationship of the disease to true hemophilia were discussed. With the knowledge that true hemophilia has never been proved to exist in females, diagnoses were made as given, but the possibility was considered that these sisters might have had true hemophilia, the first homozygous hemophilic females recorded.

Two cases of sporadic hemophilia with arthritis affecting boys were reported by Marr and Herrmann.⁴⁶⁵ The brother of one had died of hemorrhage, but no other evidence of hemophilia was found in either family. Congenital syphilis has been considered the cause of sporadic hemophilia, one of these patients had it, the other did not. Theories on etiology were reviewed.

The roentgenographic characteristics of hemophilic arthritis were summarized by Buus,⁴⁶⁶ and were as reported in previous reviews^{1, 2}. A feature "not described before" was "characteristic sharp angulations in the joint-surface, which later developed into an abrupt rectangular break in the surface, so that part of the latter sinks to a lower level."

The pathology of articular tissues was summarized by Buus, and that of hemopoietic (but not articular) tissues in three fatal cases was described by Custer and Krumbhaar.⁴⁶⁷

Treatment Of supreme importance is the control of hemorrhage. Blood transfusions were considered by some the most effective treatment.⁴⁶⁴ Vine's horse-serum treatment was helpful in one case,⁴⁶⁴ produced a severe reaction in another.⁴⁶⁷ Marr and Herrmann⁴⁶⁵ used several agents in two cases of recurrent hemorrhages. Best results were obtained by intramuscular injections of the patient's own blood. Blood transfusions were helpful, but intramuscular injections of the patient's or another's blood avoided the necessity of blood-typing. Good results were noted with protein sensitization by subcutaneous injections of sheep serum, by intramuscular injections of whole ovarian extract, or of blood from women at the beginning of menses or when pregnant. However, intramuscular injections of normal male blood were equally helpful; therefore, results did not depend on a high thrombin content of blood. Thus Birch's theory that hemophilia results from inadequate female sex hormones was considered unproved by these workers.

and others^{468, 469} Chew and his associates⁴⁷⁰ studied for about a year two hemophilic patients, first untreated, then treated with estrogenic substances by mouth and subcutaneously, corpus luteum hormone intramuscularly, and the gonad-stimulating hormone from urine of pregnant women subcutaneously. The use of these hormones did not alter the coagulation time or benefit the clinical condition. No relationship existed between blood coagulation and the amounts of urinary estrogenic substances recovered. There was more of the latter in urine from untreated hemophiles than from normal males. At times, the coagulation time of patients was greater with treatment than otherwise.

McFarlane⁴⁷¹ and Barnett⁴⁷² reported further experience with Russel's viper venom which they considered (1934) the most effective local hemostatic available. The venom possesses remarkable potency as a coagulant in "almost fantastic dilutions." In a dilution of 1:1,000,000,000 it will coagulate hemophilic blood in six minutes. The venom is used in a dilution of 1:10,000 in physiologic saline solution and is non-toxic and non-irritating. Wounds should be carefully cleaned and dressings soaked with venom solution applied, these should be kept in place and then left alone as much as possible. Alveolectomy, tonsillectomy, prostatectomy were done safely by this means. Peck, Crimmins and Erf⁴⁷³ regarded the venom of *Bothrops atrox* (Fer-de-lance) cheaper, more available and more effective than Russel's viper venom. Optimal dilution of the former was 1:10,000. Moccasin venom and a tissue extract (rabbit's lung) were ineffective.

In prophylaxis, a high-protein diet, much gelatin, and raw liver, and a diet high in vitamin B, were used by Marr and Herrmann.⁴⁶⁵

ALLERGIC, METABOLIC AND ENDOCRINE ARTHRITIS

These three "diseases" are the current ghosts of rheumatology. Their names continue to be mentioned here and there in the literature, but their form and substance are most changeable and wraith-like. One writer materializes them in the form of atrophic arthritis, in another reincarnation they may resemble hypertrophic arthritis or some other articular disease. Although heavily cloaked in conjecture and shrouded in uncertainty, they are quite respectable ghosts and sometimes appear in the best company, being approved of by scientists of standing. And it is quite possible that, in time, any one or all of them may be born with a registered name and material body, definite in their clinical picture, etiology and pathology. All the recognized arthritides have had to struggle through years of embryonic life before they were born and finally accepted.

"*Allergic Arthritis*" Almost every type of joint disease has been considered an allergic reaction. Some regard food, others bacteria as offending antigens. Some believe the arthritis is actually caused by allergic reactions. Others admit allergic manifestations are present but regard them as of secondary significance, symptoms and not the cause of the disease. Many

writers do not make the distinction clear but just discuss this or that type of arthritis as "allergic" The "allergic phases" of various arthritides were briefly noted by Brown²¹⁴ who reminded us of Turnbull's (1924) views on chronic arthritis from food allergy We have noted arguments for and against the (bacterial) allergic nature of rheumatic fever and atrophic arthritis Intermittent hydrops is regarded by many as an allergic arthritis from unknown (food or bacterial) antigens Serum sickness was again mentioned as the prime example of allergic arthritis (As a matter of fact most allergists do not consider it an "allergic" but an "anaphylactic" arthritis, an antigen-antibody reaction and not true allergy—Ed) Contributing no new data Brown argued that "in every case of arthritis" the likelihood of food or bacterial allergy should be considered and skin tests should be made with food and bacterial antigens Offending foods should be avoided and patients should be vaccinated against offending bacteria

(Most physicians do not accept suggestions such as these because of the notorious unreliability and difficulty of evaluating skin tests to food and bacteria, and because of the rarity of undoubted clinical examples of allergic arthritis in which the food or bacterial antigen was definitely identified by provocative and therapeutic tests—Ed)

Myers³⁹ suggested the following as a case of "allergic arthritis"

A 34 year old man had had attacks of pain, redness and swelling in one or both feet each fall for three years The first metatarsophalangeal joints and dorsum of the feet were chiefly involved Attacks came suddenly, lasted 5 to 10 days, and then subsided The present attack affected the right foot and great toe first, 6 days later the left foot and great toe Erythematous tender areas were noted particularly over the medial aspect of the left metatarsophalangeal joint and dorsum of the foot After two days on rest and salicylates the pain disappeared, swelling left three days later Because the patient had had recurrent asthma each winter for four years, hay fever each fall ("late August until late October") for two years and chronic sinusitis for several years, and was "skin-sensitive" to pollens of ragweed and goldenrod, Myers suggested that "the arthritic symptoms were a response to an allergin" (inferring a pollen?—Ed)

(Data are incomplete but suggest acute recurrent gouty, not "allergic," arthritis The seasonal incidence (each fall), rapid onset, involvement of great toes, erythematous tenderness at the mesial aspect of great-toe joints, the rapid full joint recovery, —all are compatible with gout Blood uric acid was not mentioned The right foot was attacked October 7, the left October 13 Had the patient's arthritis been related to pollen one might expect it to appear in August or September, not at the end of the hay-fever season Furthermore, arthritis antedated the asthma by three years and the hay fever by five Skin tests were done with pollens, not with bacteria from sinuses No provocative tests with presumably related allergens were done Had allergic arthritis been suspected, response to epinephrine might have been more immediate and instructive than to salicylates The problem of "allergic arthritis" would seem to be confused rather than clarified by such incomplete studies—Ed)

The question of "articular or periarticular hives" is raised by the case report of Dubbs⁴⁷⁴ An elderly woman with "mild recurring attacks of atrophic arthritis" and spindle deformity of finger joints developed "cold

allergy " in exposed skin, the short (5 to 10 minutes) attacks of which added other symptoms unrelated to her arthritis, such as wheals, tingling, itching, and redness, and swelling of the fingers, back and neck. These symptoms were abolished by administration of epinephrine. Dubbs considered the reaction essentially cutaneous and subcutaneous, not articular or just periarticular.

"Metabolic Arthritis" This term has never been satisfactorily defined. By it one writer means "atrophic," another "hypertrophic" arthritis. Still others mean "gout" or "articular pains with hypo- or hyperthyroidism." Under the broad definition of "metabolism" many if not every arthritis is a "metabolic" arthritis, but by a narrower definition it would be an arthritis due to some recognized abnormal metabolism of food. No definite consistent metabolic error has ever been identified with any of the arthritides except gout and alkaptonuria and, even here, the nature of the fault is very obscure. The year's literature added nothing to justify the term.

"Endocrine Arthritis" This term has been variously used also as a synonym for almost every type of arthritis. Particularly confusing is the term "menopause arthritis" which is applied by one writer to cases of atrophic, and in other instances to hypertrophic, arthritis appearing near the menopause. Others give it a special meaning—a villous synovitis of knees in women about the menopause, but definitive clinical and pathologic data are not at hand. Since most of the arthritides are general diseases, sometimes with extensive secondary physiologic disturbances, it is not surprising that disturbances in endocrine function are found, but no consistent etiologic relationship between any form of arthritis and any recognizable endocrine disturbance has been proved.

Robinson³⁴⁰ accepted Llewellyn's conception of "menopause arthritis"—villous synovitis in traumatized joints, especially knees, with hypothyroidism prior to the menopause. "It may come on several years before or round about the time of the cessation or several years afterwards" (The vague time relationship alone would seem to refute the appropriateness of the term—Ed.) Periarthritic fat pads give an appearance of joint enlargement, the cavity is distended with synovial proliferations or fluid. The joints creak and revealipping of bone in roentgenograms. Robinson (1926) reported cases affecting young women with amenorrhea which were relieved when menstruation was restored by intrapelvic diathermy, of which he again approves. To many the syndrome is identical with hypertrophic arthritis, but Gray²⁵¹ accepted it as a separate entity.

The relationships between chronic arthritis, hyperthyroidism, and myxedema were discussed by Monroe²⁹⁶. According to another²⁹⁵ atrophic and hypertrophic arthritis are badly mixed up with the endocrines.

Relation of Arthritis to Parathyroids, Parathyroidectomy for Arthritis Because he found hypercalcemia and decreased electromuscular excitability in some cases of "ankylosing polyarthritis and spondylarthritis," Oppel (1926) suggested that these diseases were due to hyperparathyroidism and

proposed parathyroidectomy therefor. The idea was advanced by certain French and Russian workers and by Ballin and Morse (1931) in this country, but it has been sharply denounced by many. Schkurov²⁰⁸ reported results of "parathyroidectomy" in 83 cases (or 86, both figures are given) of "chronic rheumatic polyarthrititis and spondylarthrititis." Values for blood calcium before operation ranged from 8 to 17 mg, after operation 7 to 15 mg per 100 cc. Blood calcium before and after operation, respectively, was below 9 mg in 6 and 16 per cent, between 9 and 10.9 mg in 52 and 55 per cent and 11 mg or above in 42 and 29 per cent. Thus there was a postoperative shift from high to normal and from normal to sub-normal values for calcium. Immediate results from the operation were noted "in all cases" less muscle and joint stiffness and pain, and increases of 10 to 55° in joint motion. The results six months to four years later were noted in 40 cases. They were "good" (subjective and objective improvement) in 55 per cent, "satisfactory" (subjective relief only) in 35 per cent. Four patients were unrelieved or were worse. Schkurov concluded that parathyroidectomy cannot affect existing ankylosis but prevents ankylosis and will "do away with rigidity of joints."

(Containing conflicting statements, poor arithmetic, shifting premises and conclusions impossible of acceptance, this report is open to sharp criticism. It is our opinion that if any significant relief was obtained it was not from parathyroidectomy or any associated alteration in calcium but was in all likelihood entirely non-specific—the temporary relief which may follow, sometimes dramatically, almost any surgical operation. Schkurov reported hypercalcemia in 42 per cent of his cases. The method is not stated and the figures seem questionable since many excellent investigators have failed to find hypercalcemia in arthritis, except in rare cases. No metabolic studies, data on blood phosphorus or phosphatase, or urinary calcium and phosphorus were reported. He says "An important objective effect of parathyroidectomy is the decrease of blood calcium." But 52 per cent of his patients had a normal blood calcium before operation and only 3 per cent more [55 per cent] had normal values after operation. Parathyroidectomy was done in cases with and without hypercalcemia, yet admittedly results were the same in each group. But because some who had normal blood calcium were benefited he then advocated surgery for patients with rigidity of joints or a "tendency to ankylosis" even if the calcium was normal.)

He stated subjective improvement was obtained "in all cases," but this would then include one case in which "the patient did not feel any improvement for an entire year, but afterward pain subsided and mobility of joints was increased." Although "all" patients obtained immediate improvement, results six months to four years thereafter were only "good" in 55 per cent, and if the following is a representative case this figure is also open to question. A young woman had "contractions of the hip, both knees, elbows and wrist joints. Before operation she walked in a squatting position with the help of legs and hands—almost creeping. After parathyroidectomy and subsequent treatment by extensions" there resulted "an almost complete correction of all deformities" and "full restoration of all movements of joints." It is difficult to believe this, or certainly to ascribe it to parathyroidectomy rather than to manipulations.

The statement most destructive to his proposition was that in 23 [or over a fourth] of the 83 cases "histologic examination [of tissue removed at operation] did not

show any evidence of parathyroid gland tissue," in spite of which several had subjective improvement and a lowered calcium. We cannot understand why he included them in a discussion on parathyroidectomy and statistical results therefrom. Obviously, results could not possibly be from parathyroidectomy [which wasn't even done in 28 per cent] or from the inconsistent shifts in blood calcium. In some cases edema of the feet completely disappeared after operation, but in at least one case it reappeared when the patient began to walk. This too suggests that results were non-specific from an operation, from bed rest, relief of trauma and of static edema—Ed.)

At first Schkurov suspected the results were due to suggestion, not to parathyroidectomy. He discarded this idea when autohemotherapy without parathyroidectomy gave no relief. Having also noted relief even when removed tissue contained no parathyroid tissue, Simon and Weil (1932) ascribed it to removal of thyroid tissue or of fat. This led them to make a simple skin incision without touching the parathyroids; results were also satisfactory. Bach²⁹⁷ and Rankin⁴⁷⁵ criticized Oppel's work, stating that no metabolic studies were done, that the diagnosis was made on single determinations of serum calcium, that at operation parathyroid tissue was not always removed or even identified, and that symptoms often recurred rapidly. The fact his results were as good whether parathyroid tissue was removed or not, Oppel considered was because operation produced parathyroid ischemia by interfering with the nerve and blood supply. According to Bach equally good results were obtained by Weill who merely exposed the glands, and by Simon who applied chemical irritants to the thyroid gland. Those who have performed parathyroidectomy have claimed that if the operation is successful, on the same evening or on the day after, pain and periarticular swelling are markedly diminished and movements which were formerly painful become painless.

(These same dramatic, but generally temporary, results have been reported after removal of teeth, tonsils, appendix, gall-bladder, spleen, sympathetic ganglions, and other tissues. Bach²⁹⁷ noted similar dramatic results after thyroidectomy—Ed.)

Authors with a large experience with undoubted hyperparathyroidism in this country (Bauer,⁴⁷⁶ Bauer and Camp,⁴⁷⁷ Lahey and Haggart,²⁷¹ Mason and Gunther,⁴⁷⁸ Rankin⁴⁷⁵) all agree that parathyroidectomy cannot be sanctioned for arthritis and that "ankylosing arthritis" is not from hyperparathyroidism. One cannot even justify exploring the parathyroid glands of patients with skeletal changes until one has obtained chemical or pathologic evidence that such changes are due to hyperactive parathyroid tissue. In a study of 200 patients with atrophic arthritis Lahey and Haggart found no evidence whatever of hyperparathyroidism. Serum calcium and phosphorus were consistently normal and roentgenograms never revealed features of hyperparathyroidism. In 100 cases of atrophic and hypertrophic arthritis Hartung and Greene²⁵⁸ found no evidence of hyperparathyroidism in 97 per cent the blood calcium was normal.

Although the two diseases are unrelated, the skeletal pains of hyperparathyroidism are sometimes diagnosed "rheumatism" or "arthritis." In

hyperparathyroidism the shafts of bones are involved in local and generalized softening, destruction and cyst formation. Current reports gave details of about 50 cases. In at least 14 symptoms included pains in legs, arms, thighs, and lower back, and sometimes in hands and feet. Some of these cases were frankly considered arthritic until the characteristic roentgenographic and chemical alterations of hyperparathyroidism were discovered. The latter are fully discussed in several good papers (Albright,¹⁷⁹ Bauer,⁴⁷⁰ Bauer and Camp,⁴⁷⁷ Borg,¹⁸⁰ Castleman and Malloiy,¹⁸¹ Cuthbertson and Mackey,⁴⁸² Lahey and Haggait,²⁷¹ Left, Blanchard and Peabody,⁴⁸³ Mason and Gunther,⁴⁷⁸ Quick et al,⁴⁸¹ Rankin,¹⁷⁵ Robbins,⁴⁸⁵ Taylor⁴⁸⁶)

MISCELLANEOUS TYPES OF JOINT DISEASE

Hemorrhagic Villous Synovitis due to Xanthoma Kling and Sashin⁴⁸⁷ reported one case. A knee was painful for two years. Hypercholesteremia (238 to 288 mg per 100 cc) was repeatedly present. Presumably a disturbance of lipid metabolism caused lipid precipitation and xanthoma formation. Synovectomy gave relief. Twenty cases previously reported were reviewed. Symptoms resemble those of inflammation or internal derangement. Preoperative diagnosis may be made by finding an increased bilirubin and cholesterol content in the effusion.

Synoviomias (Benign and Malignant) Tumors of articular structures other than bone are rare. Synoviomias apparently originate from capsule or synovial membrane of bursae or joints, usually a knee. Less than 100 synoviomias have been reported (Razemon and Bizard, 1931) of which 43 were benign, 29 malignant. They may grow slowly and be regarded as "synovitis" for years before being correctly diagnosed. Amputation is often necessary. Coley,⁴⁸⁸ Wagner⁴⁸⁹ and Adair⁴⁹⁰ reported several cases, and discussed their pathology and treatment. A malignant synovioma may invade bone, but it does not produce osteoid tissue although it has the objective characteristics of a bone tumor. Hodgson and Bishop⁴⁹¹ saw one affecting a man aged 28 years. His left knee was affected by a rapidly-growing tumor which soon metastasized to adjacent skin and lymphatics. Roentgen therapy and Coley's toxin were useless, the patient died in seven months.

Anomalous Synovial Cysts Black⁴⁹² found two such cysts during classroom dissection. One cyst, 18 by 15 by 10 mm, was on the dorsum of the hand of a young laborer, between the first and second left metacarpals, and was inconspicuous until superficial fascia was removed. It did not connect grossly with synovial membrane of joints or tendon sheaths. The other cyst (16 by 10 by 8 mm) formed an obvious swelling on the medial side of the fourth left phalanx proximal to the first interphalangeal articulation. It originated probably from a knife-stab.

Tenosynovitis This most often affects a wrist or the peroneal tendons in the leg. Splints on lower extremities are cumbersome. Fieldman⁴⁹³

recommended the use of Unna's Paste Boot such as is used for varicose veins. It produces the least limitation of motion.

Cysts of Fibrocartilages of Knee Joint Fifty cases reported to 1930 were reviewed by Taylor¹⁹⁴ who reported four more. Cyst formation in menisci are commoner (72 per cent) in men than in women (28 per cent), in external more often (82 per cent) than in internal cartilages (18 per cent). Trauma is the usual cause. Menisci become contused. A degenerative process in fibrocartilages results in multilocular cysts. Symptoms are localized pain, swelling and sometimes stiffness. Treatment is removal of the entire cartilage. Lesser procedures (removing or curetting cysts) are followed by recurrences.

Leukemia Resembling Rheumatic Fever Some children with leukemia have fever and migratory joint pains without visible inflammation or roentgenographic changes. Others have acute arthritis with inflammation, roentgenograms showing focal areas of bone absorption, periosteal elevation and other changes. When cardiac murmurs from anemia are present and enlargement of lymph nodes and spleen is absent, the condition often resembles rheumatic fever before the blood picture becomes definite. Diagnosis may be suspected from the lack of effect of salicylates, it is eventually made on the appearance of abnormal leukocytes in blood. Three new cases of lymphatic leukemia resembling rheumatic fever affecting children were recorded by Smith¹⁹⁷.

Keratoderma with Arthritis Hyperkeratosis of skin and nails with arthritis may occur in gonorrhea—keratoderma blenorrhagica. Patel⁴⁹⁵ saw an unusual case of keratoderma and arthritis affecting a Mohammedan boy without history, signs, or symptoms of gonorrhea. This boy, aged 9 years, noted painful swelling of several joints and painless nodules on his legs. Recurring fever, progressive cachexia and arthritis developed. Examination two years later revealed arthritic dislocation of the right knee and a wrist, flexion deformities of an elbow, both hips and left knee, huge rupia-like keratoid masses of growth on both legs—painless, hard to touch and brownish, and hypertrophy of nails. There was no evidence of syphilis. Interesting photographs were shown.

Mycotic Infections Meyer and Gall⁴⁹⁶ reviewed 60 reported cases of mycosis of the spine: 47 from actinomycosis, 12 from blastomycosis and one from sporotrichosis. Mycotic spondylitis is generally secondary to a primary respiratory or intestinal focus. Vertebrae are infected either by direct contact with a suppurating focus (in which case the external surfaces of vertebrae are eroded), or by vascular metastasis (in which case bone destruction is central and surrounded by a condensed ring of bone). Symptoms may be slight or marked. In these 60 cases a clinical diagnosis was made in only nine. Diagnosis is very difficult and not often made until late in the disease or until death. Mortality was 90 per cent.

In mycotic spondylitis involvement of intervertebral cartilages and the formation of osteophytes and periosteal inflammation are not generally seen.

The disease is generally mistaken for Pott's disease, from which it can be differentiated as follows: in mycosis the angular deformity typical of Pott's disease is most often absent because of the capsule of dense bone which surrounds the destroyed area and prevents flattening of vertebral bodies. Mycosis reveals multiple sinuses, more destructive invasion and a more rapid opening of abscesses than in Pott's disease. The skin lesions in mycosis are characteristic. Roentgenograms in mycosis show the following, none of which are often seen in Pott's disease: cortical erosion of vertebrae, also erosion of articular processes and pedicles, and cavity formation in the cancellous portion surrounded by a zone of increased density.

About 45 cases of *Torula* infection in man have been reported. Usually the nervous system, rarely the skeletal system, is involved. A young man seen by Kessel and Holtzworth¹⁹⁷ bruised a knee slightly. It became increasingly painful, swelling, effusion and flexion deformity ensuing. At arthrotomy *Torula* organisms were recovered, and animals inoculated therewith developed lesions. The patient developed *Torula* lesions of both breasts, but these responded to roentgen therapy. The granulomatous condition of the knee did not respond to treatment and amputation was necessary a year later.

Arthrokatachysis of Hip Joints Levinthal and Wolin⁴⁹⁸ reported five cases. This imposing name means "subsidence or sinking-in of a joint." It is not a specific disease but a feature which may occur "in osteo-arthritis, gout, gonorrhea, syphilis, tuberculosis, trauma or endocrine disturbances." It was previously called "osteo-arthritic protrusion or intrapelvic protrusion of the acetabulum (Otto pelvis)." The characteristic feature is protrusion of the acetabulum into the pelvis and a narrowed hip joint space. It results from weight bearing and muscle pressure at the diseased joint. The femoral head bores its way through a weakened acetabulum into the pelvis. Symptoms are those of progressive chronic arthritis. Roentgenograms are characteristic: deepened acetabulum, thinning of the medial and inferior wall, eburnation, and narrowed space. If conservative treatment (heat, massage, traction) fails, casts or braces, arthroplasty, or arthrodesis, are indicated.

"A Syndrome of Unknown Etiology" Christian⁴⁹⁹ summarized reports of two patients who had long continued fever with inflammation of serous and synovial membranes (pleurisy, pericarditis, arthritis) and who eventually died of glomerulonephritis. Numerous laboratory tests failed to elicit the causal infection. The two cases were previously described by Tremaine (1934) as "Subacute Pick's Disease (Polyserositis) with Polyarthritis and Glomerulonephritis." (Christian noted that some patients have skin lesions suggestive of lupus erythematosus. To us the cases seem to be of acute, lupus erythematosus disseminatus, one with and one without skin lesions.—Ed.)

Acute Postoperative Arthritis Some cases were identified by Coburn and Paul¹⁷⁸ as recurrences of rheumatic fever provoked by surgical operations. Of cases of acute postoperative arthritis seen by Hench^{49, 106} a few were of rheumatic fever but the great majority were gouty arthritis, clinically

proved by past histories, physical and laboratory signs of gout, and response to treatment

DISEASES OF MUSCLES, FIBROUS TISSUE AND BURSÆ

Introduction Classification A study of diseases of muscles is largely an excursion into the unknown⁵⁰⁰ Various classifications of such diseases are in vogue

Shelden⁵⁰⁰ classified them briefly into (1) conditions in which disease of muscles is incident to a general infection (for example, rheumatic fever), with convalescence muscles recover rapidly and no special attention is paid them, fortunately, the muscular system generally has a high degree of immunity to infections which affect other organs, hence muscles are but infrequently and transiently involved, (2) diseases peculiar to muscles themselves, which are rare but important and include acute and chronic (true) myositis, dermatomyositis, myasthenia gravis and the neuromyopathies Ornsteen⁵⁰¹ approved Batten's (1904) classification of inflammatory diseases of muscles (1) primary infections, (a) acute polymyositis, dermatomyositis, hemorrhagic myositis, polymyositis with erythema multiforme and urticaria, and pseudotrichinosis, (b) neuromyositis, (c) tuberculous myositis, (d) syphilitic myositis, and (e) myositis with trichiniasis, (2) secondary infection in the course of acute or chronic disease, (a) myositis with specific fevers (typhus, typhoid, smallpox), (b) infective myositis with pyemia, infective endocarditis, glanders, gonorrhea, puerperal infection, infected wounds, actinomycosis, erysipelas, etc., and (3) myositis with special terminal lesions, (a) myositis ossificans progressiva, (b) general or localized myositis fibrosa

(The necessity of using a classification 32 years old is evidence of lack of progress in this field This classification does not specifically mention the common form of "myositis," every-day muscular rheumatism (intramuscular fibrositis) In discussions of "Myositis" one must distinguish between (1) "true myositis," parenchymatous diseases of muscles where definite primary pathologic lesions of muscle cells are seen, and (2) interstitial muscle disease, in which primary lesions are almost if not entirely in supporting fibrous tissue and in which muscle cells are rarely ever involved in demonstrable disease except slightly and secondarily This form or forms, Gowers, Stockman and others have called "intramuscular fibrositis"—Ed)

FIBROSITIS

Fibrositis is an inflammation of connective tissue Common sites for fibrositis are in deep fascia, muscle sheaths, subcutaneous tissues and fibrous portion of joint capsules and related ligaments Classified on anatomic grounds the main forms are panniculitis (fibrositis of subcutaneous tissue), bursal or tenosynovial fibrositis, fascial and intramuscular fibrositis, periarticular fibrositis, and perineural fibrositis^{337, 388, 441} On etiologic grounds it is classified as infectious or toxic, and traumatic (Telling⁵⁰²) or as in-

inflammatory fibrositis (from infection, toxins, or trauma) and degenerative fibrositis (from tissue age) (Buckley³⁸⁸)

Etiology and Pathogenesis Since inflammatory reactions in fibrous tissue are common to many "rheumatic" and other diseases, some writers do not without a pathologic basis, speak of fibrositis of rheumatic fever, of gonorrhea and so on (Telling⁵⁰²) Forms of fibrositis are undoubtedly a part of these diseases, but these are thought of as secondary fibrositis in association with a dominant, recognized clinical syndrome When writers speak of "fibrositis" they usually mean a primary form—disease of fibrous tissue independent of disease elsewhere Precipitating factors are given as influenza and respiratory infections, thermal and barometric changes, acute injury or chronic strain Actual causes are given as general or focal infections, "intestinal toxemia," "metabolic derangements," physical fatigue³³⁷ In many cases the cause is unknown Chilling and climatic change are regarded by some^{442, 502} as primary causes, but Buckley³⁸⁸ considers them only precipitants "Damp and cold will never cause more than passing stiffness in the absence of toxic substances, whether these are bacterial or metabolic in origin"

The pathogenesis of the disease involves an inflammatory exudate which may produce transient symptoms and then resolve If resolution does not occur, the exudate becomes organized and gives rise to nodules, cords or bands in muscles or large indurated areas with painful tender spots³³⁷

Symptoms The symptoms are pain, stiffness, soreness, tenderness of affected tissues, and sometimes spasm of related muscles Pain may be continuous or intermittent, sharp or dull Stiffness and pain are often worse on waking in the morning and after an hour or so of inactivity during the day, but lessen after moderate activity Such "jelling" is presumably due to the results of capillary congestion that accompanies inactivity and is relieved by some motion⁵⁰² Fibrositis may be diffuse, affecting various anatomic regions, but is usually localized Local varieties often have separate names as each has its special symptomatology, they are described by Alexander,³³⁷ Buckley,³⁸⁸ Telling,⁵⁰² and Willcox⁴⁴¹

Panniculitis may be widespread or localized to thighs or neck When the neck is affected aching pain occurs in the occipital region and extends over the vertex "fibrositic or indurative headaches" Telling considers them the commonest type of chronic or intermittent headache, "the four diagnostic features of which are persistency, thickening, nape-of-the-neck location, and tenderness" Pain is variably persistent and intense Many cases of pleurodynia, fibrositis of the chest, are diagnosed angina pectoris Certain vague abdominal pains are due to fibrositis of the rectus or other muscles In abdominal fibrositis pain and tenderness are elicited by "finger tip pressure" rather than by "flat-hand pressure", tender spots are more or less localized, but may be multiple and occupy positions not usually affected by visceral disease, muscle rigidity (usually present in the latter) is absent and pain may be intermittent and affected by weather

Perineural fibrositis generally affects brachial or sciatic nerves and is often called "neuritis," a misnomer unfortunately sanctioned by physicians. In "brachial perineuritis" there is tenderness over the brachial plexus above and below the clavicle and pain when the arm is abducted. Pain follows the distribution of nerves affected. "Brachialgia" may be associated with fibrositis of the subacromial bursa, deltoid muscle, or long head of the biceps. Many cases of sciatica are from perineural fibrositis, which may accompany lumbosacral and sacro-iliac disease and strain. Gluteal fibrositis may be present with or without sciatic fibrositis, as may lumbar fibrositis (lumbago) also. Telling believed there were more cases of fibrositic "trigeminal" neuralgia than of true trigeminal neuralgia.

The two commonest forms of fibrositis are the localized or diffuse intramuscular fibrositis ("myalgia," "neuromuscular pain," "muscular rheumatism"), and periarticular fibrositis ("arthralgia," "capsular rheumatism"). (Without further definition the term "arthralgia" has been used herein by several writers [Gray,²⁻¹ Monroe,^{-9c} Dreyer and Reed³³¹] who contrasted it with atrophic or hypertrophic arthritis. May one assume that periarticular fibrositis was present?—Ed.) Willcox⁴⁴¹ and Hench¹⁰⁶ emphasized the importance of differentiating the latter from "arthritis" which it is usually erroneously called. Symptoms of periarticular fibrositis are stiffness and soreness of joints, particularly after sleeping or resting, tenderness which is often evanescent, and pain often brought out only when the capsule is stretched. Symptoms are marked by variability and transiency but may be continuous. Differentiation from arthritis rests on persistency with which sedimentation rates, roentgenograms, blood counts, and weight curves are normal and on the general absence of muscle atrophy, deformity, and significant swelling. When "swelling" is present it is usually slight, localized and extra-articular, more of a "thickening" than actual swelling, and hydrops is absent (Hench¹⁰⁶).

Some writers make much of the nodules of fibrositis which to others seem "only accessible to the finger of faith." Because some consider it difficult to locate nodules or to demonstrate pathologic changes in tissues removed at biopsy, fibrositis has been defined as a "disease which physicians found but surgeons rarely find" (Telling⁵⁰²). Fibrositic indurations may be non-nodular (as strands, tracts, sheaths) or nodular. Of the latter there are presumably three kinds: large nodules (generally in fibrous aponeuroses), small nodules (generally in muscle bundles), and "myogeloses." The last are small sharply-localized areas of hardening in muscles, chiefly gluteal, which Lange (1931) and Nicola (1932) ascribed to local chemical disturbances, possibly local accumulations of lactic acid, and which are "negative" on biopsy. The nodular indurations consist presumably of inflammation of the perimysium and vary in size "from a pea to an almond" (Sutro⁵⁰³). Obvious visible nodules are the exception, not the rule as some have led themselves to expect⁵⁰². Cyriax⁵⁰⁴ believed that around most of the nodules are small localized muscular contractions, and that when

nodules rapidly "disappear" under various measures, it is the muscular contraction that disappears, leaving a residual nodule too small to palpate.

Pathologic Studies Such studies have concerned nodules more than other tissues. Nodules consist of "fibrous septa enclosing muscle fibers and bundles of characteristically vague and ill-defined outline," according to Telling⁵⁰² who stated that nodules of fibrositis are different in anatomy, pathology, and distribution from the nodular formations of rheumatic fever, which are "still further differentiated by being absolutely painless, even on palpation."

The small or fairly large subcutaneous nodules frequently found in sacro-iliac regions are regarded by many as evidence of fibrositis, active or old. They may be painless or painful depending on the stage of inflammation therein. Because they are often found in patients who give no history of fibrositis, some regard them as of no significance. Among 170 unselected hospital patients with various complaints Sutro⁵⁰³ found subcutaneous nodules, generally over sacro-iliac joints or near the tips of the lumbar spinous processes, in 94 cases (unilateral in 45, bilateral in 49). Thirty-three of the 170 patients had low backache, 10 had no nodules, and 16 had tender and seven non-tender nodules. Tender nodules were removed in four cases. One patient was a woman with low backache and sacro-iliac arthritis; she claimed complete relief after nodules were removed. One was a patient with subastragalar tuberculosis and no backache. One patient had a low backache and sacro-iliac arthritis, the backache persisted after operation but local tenderness disappeared. One patient had a low backache, sacro-iliac arthritis and no postoperative relief. Examination of the nodules in these four cases showed them to consist of lobules of adult fat of normal appearance without signs of recent or old inflammation or other evidence of metabolic or toxic disturbance. Sutro concluded that they were "protective buffer-pads over poorly muscle-covered areas of sacrum and ilium," that they were not part of any recognized disease and may be found in apparently normal persons, and that they were wholly different from those of rheumatic fever, atrophic arthritis, and syphilis.

(This study represents a laudable beginning but does not settle the issue. The relief which two of the four patients obtained by removal of nodules is not explained nor is the tenderness of the nodules. Many more nodules in various stages of tenderness and formation should be examined, as well as sections of adjacent fibrous tissue. It is difficult to believe that such nodules are "normal" even if they are often symptomless and in patients who give no history of fibrositis—Ed.)

Laboratory Data Of 68 patients, 36 per cent had an abnormal levulose tolerance test²⁹¹. In five cases the average values for albumin, globulin and total protein of blood were a little below normal²⁵⁷. Blood groups were normally distributed²⁶⁰.

Treatment This follows the same general principles as in atrophic arthritis. Removal of foci is advised^{388 502}. Vaccines seemed valueless to some,³⁸⁸ helpful to others¹⁰⁶. Buckley³⁸⁸ considered protein therapy useful,

and for empiric reasons advised the use of onions and garlic in diet. In some cases the affected part must be rested with slings and strapping, but rest is not indicated for fibrositis of neck and chest, according to Telling.⁵⁰² Various forms of physical therapy were employed³³⁷ short wave diathermy,^{17, 18, 356, 505} Fango,³⁵² histamine ionization,^{17, 320, 388} paraffin baths, pelvic diathermy⁵⁰⁸ and fever therapy^{48, 74}. "The only curative therapy" is massage, according to many^{254, 502}. Massage should be light over affected tissues, except nodules "which can be rubbed away"³⁸⁸. Tender nodules were surgically removed by Stockman⁵⁰⁷. For associated fatigue, glycine (amino acetic acid) has been tried with variable results.⁵⁰⁸

Epidemic Myalgia Carney⁵⁰⁹ saw 87 cases of epidemic pleurodynia in one month in West Virginia. Typical symptoms were fever, rapid pulse and respiration, pain at the attachment of the diaphragm to the anterior abdominal wall, or at times in the epigastrium. Pain was greatly aggravated by respiration. The disease usually ended in about 24 hours. A plasmodium was suspected.

Noting the frequency with which persons suddenly developed one-sided "stiff neck," Massell and Solomon⁵¹⁰ questioned 61 patients and 52 hospital colleagues who had recently suffered therewith. Symptoms were usually noted on waking, were occasionally gone by noon, generally lasted one to two days subacutely, and in some cases hung on mildly for several days or weeks. Sites of maximal pain in order of frequency were the origin of the trapezius muscle at the superior nuchal line, half way down the neck along the border of the trapezius, at the insertion of the sternocleidomastoid muscle, and at the lower border of the trapezius at the shoulder. No nodules were felt. Heat gave relief, massage was painful but gave more relief. Treated patients had the condition as long as the others, however. A hypothetical "twist of the neck while asleep" or "exposure to draft" did not seem as likely a cause as an epidemic infection, suspected but not investigated. The attitude of physicians to "epidemic benign myalgia" should not be the same as that of patients—one of annoyed tolerance and resignation.

(The inquiry, being mostly of the questionnaire type, did not escape the inadequacies inherent therein—Ed.)

Myositis Ossificans Three types were mentioned (1) progressive, (2) circumscripta, (3) post-traumatic. Studies on a patient with the progressive type convinced Wilkins and his colleagues⁵¹¹ that phosphatase is intimately associated with the ossification. At various stages of the disease biopsies were made on normal and affected tissues. Serum calcium, plasma phosphatase, and inorganic phosphorus were normal. Total and inorganic phosphorus of diseased muscle was much lower than in normal muscle. The phosphatase activity of affected muscle in the pre-ossification stage was 800 to 1,600 times that of normal muscle, and several times that of normal bone, that of heterotopic bone was much higher than that of normal bone.

Features of a case of traumatic myositis ossificans, reported by Taylor, Shea and Argyr⁵¹² included contusion, swelling, induration, limitation, tenderness and palpation of a hard mass which could be rotated around the bone shaft. Serial roentgenograms reveal a mass of increasing density separated from the bone shaft. As density increased the mass showed lamellae corresponding to ossification of muscle bundles or fascial layers. Osteogenic sarcoma is differentiated from myositis ossificans in that the former progresses instead of regressing after four to six weeks, is usually near the epiphysis, and becomes connected with the bone. Treatment of traumatic myositis ossificans includes rest, heat to promote absorption of the hematoma, and excision if function is disturbed.

Chronic Generalized Fibromyositis (Progressive Myositis Fibrosa) Few cases have been reported. In one case recorded by Ornstein⁵⁰¹ hardness and stiffness of muscles of limbs, back and abdomen, severe muscle spasms, myotonia, sweats, rapid respiration and pulse, and loss of weight of one year's duration were present. Creatinuria was absent. Biopsy of muscle showed a marked increase in subcutaneous fibrous tissue and severe scattered degenerative changes in many muscle cells. "Absence of skin lesions differentiated it from dermatomyositis." The differential diagnosis and a review of reported cases were discussed.

Dermatomyositis This was the suggested diagnosis in a case seen by McAlpine⁵¹³. Pain behind the knees, and later diffuse swelling of legs, hands and forearms were present. These subsided and progressive stiffness and weakness of the hands ensued. Muscles of the hands, forearms, and legs and the rectus muscle were hard. Leukocytes numbered 14,500 to 18,000 per cu mm blood, eosinophiles comprising 33 to 37 per cent. Biopsy revealed increases in sheath nuclei but no giant nuclei, Trichinella or marked inflammatory infiltration.

Miscellaneous Myopathies Features of myasthenia gravis and various muscular atrophies were reviewed by Ains and Cobb⁵¹⁴. Myopathies can be separated into two groups, according to Milhorat and Wolff⁵¹⁵ (1) those in which creatinuria is marked and creatine tolerance grossly deficient, a deficiency exaggerated by the administration of glycocoll, and (2) those in which creatinuria is slight and the creatine tolerance is slightly deficient and not exaggerated with glycocoll.

Traumatic Injuries to Muscles and Tendons Clinical features and differentiation of various traumatic lesions were described by Haldeman and Soto-Hall⁵¹⁶. Symptoms common to most ruptures were sudden sharp pain or "snap" during violent effort, inability thereafter to perform certain motions, and the appearance of ecchymoses and a defect in muscle or tendon. A lightly-exposed roentgenogram may show a defect in muscle shadow or a chip of bone torn from a tendon insertion. Application of faradic currents to a ruptured muscle causes it to contract with pain at the site of tear. Injections of procaine hydrochloride into the subdeltoid bursa helped to dif-

ferentiate between bursitis with reflex spasm of the supraspinatus muscle, and tears of the supraspinatus tendon. If the former is present the arm can be abducted actively and painlessly a few minutes after injection, if the latter is present active abduction is not improved. In the lower extremity the quadriceps, and in the upper the supraspinatus, muscle or tendon is most likely to be torn, especially in the supraspinatus muscle, degenerative changes of advancing age (fibrillation or fraying, even perforation of the supraspinatus tendon into the joint) play a predisposing rôle.

Subdeltoid Bursitis This results from trauma more often than from allergic, toxic or infectious agents, in Palmer's ⁵¹⁷ experience. Diathermy was most helpful if small rounded electrodes were used and properly placed. Rest and ultraviolet irradiation were also used. Of 65 patients, 32 were men, 33 women, the age incidence was 25 to 71 years. Forty-seven patients who were relieved received an average of 16 treatments. Patients with calcified subdeltoid bursitis (post-traumatic?) were frequently notably relieved when Haldeman and Soto-Hall ⁵¹⁶ injected 10 to 15 c.c. of 1 per cent procaine hydrochloride into the bursa. Calcium deposits sometimes disappeared within a few days. Often no other treatment was necessary. Injections were sometimes repeated. (Such calcium deposits sometimes rapidly disappear spontaneously—Ed.) Others advocated short wave therapy, ^{518, 519, 520} histamine iontophoresis, ^{517, 520} massage and manipulation ⁵¹⁰

MISCELLANEOUS CONDITIONS

Bunions Bunions may seem of minor importance, but they are painful, crippling, deforming and unsightly. Stanley and Breck ⁵¹⁸ operated on 211 bunions (129 patients) by the Petersen-Fowler-Singley procedure—a web-incision between the great and second toes. After backward and mesial disarticulation of the great toe the exostosis was removed with "uniformly good results." In 20 years' experience no patient needed a second operation or complained of a poor result. (They were California State prisoners—Ed.) The operation had these advantages: the technic is simple and trauma slight, the scar is not exposed to subsequent trauma from shoes, the weight-bearing buttress of the joint is undisturbed, the period of disability is minimized and danger of ankylosis is negligible.

Osteopoikilosis (Bone Speckles) This represents an asymptomatic familial anomaly of bone discovered accidentally in roentgenograms. Small circumscribed areas of increased density (2 to 5 cm. in length) may appear almost anywhere in the skeleton. In some cases dark vertical striations giving shadows much denser (less opaque) than normal bone are seen. Sutherland ⁵¹⁹ reviewed the 32 reported cases and discussed the relation of osteopoikilosis to melorheostosis and chondiodysplasia. (An additional case was presented, that of a young man with multiple areas of circumscribed mottling in many bones. Linear striations [10 mm. long, 5 mm. wide] were also seen in diaphyses of tibia and fibula. Blood calcium, phosphorus and phosphatase were normal. His mother and a brother were similarly affected—Ed.)

Multiple Myeloma Cases of myelomatosis may present features resembling hyperparathyroidism. Such a case was seen by Enzel and Lieberman.²⁰ An elderly man developed low backache and lost 30 pounds (13.6 kg). Marked emaciation, a tender lumbar spine and sacro-iliac joints, and Heberden's nodes were noted. Roentgenograms revealed multiple areas of bone destruction in spine, pelvis and femurs, and (unrelated) hypertrophic arthritis. Bence-Jones albumose was not found (one test). Blood calcium was 11.8 to 13.7 mg and phosphorus 3.2 mg per 100 c.c. A negative calcium balance was present (in the diet 200 mg, in urine 530 mg). Hyperparathyroidism was suspected, but at operation no tumor was found. Postoperative pneumonia was fatal. Necropsy revealed myelomatosis and marked parathyroid atrophy (presumably from functional hyperparathyroidism).

Differentiation Cases of hyperparathyroidism generally have an elevated serum and urinary calcium, a normal or low serum phosphorus. Sometimes serum calcium is normal. In myelomatosis hypercalcemia may also appear, but serum phosphorus is generally normal or high. Serum phosphatase is generally high in hyperparathyroidism, normal with myeloma. Bence-Jones albumose is not always present in myelomatosis and may be present in other diseases (including hyperparathyroidism^{47,48}). A negative calcium balance may be present in both. Differentiation, therefore, may be difficult and should be made only after comprehensive, and not superficial, clinical, chemical, radiologic and metabolic studies, with biopsy if necessary.

PHYSIOLOGY OF ARTICULAR TISSUES

Collins²¹³ found that, in general, the chemistry of synovial fluid is the same as that of the patient's blood. Differences in sugar and protein concentrations may be found. Synovial fluid sugar is apt to be much lower than blood sugar in cases with infected synovial fluid but not in those in which fluid is sterile even though it has a high cell count. Thus a synovial sugar of 50 mg or more below the blood sugar level is strong evidence of bacterial invasion of the fluid. Total proteins are increased in most effusions, especially with many cells. Consistent increases in protein and cell count in fluid in atrophic arthritis indicate an exudate, not a transudate, is present. Studies on synovial cytology were more helpful than those of synovial chemistry. Six types of cells are commonly found: polymorphonuclears, eosinophiles, lymphocytes, monocytes, macrocytes (large phagocytic cells) and synovial lining cells. The total cell count and percentage of polymorphonuclear cells vary in different diseases (table 2). Whereas the normal synovial fluid contains "about 200 cells" per cu. mm. of which less than 10 per cent are polymorphonuclears, joint fluid in atrophic arthritis contains 5,000 to 60,000 nucleated cells, of which generally 70 to 90 per cent are polymorphonuclears. Total and differential counts were much lower in hypertrophic than in atrophic arthritis, and only slightly altered in intermittent hydrops and in "sympathetic joint effusions"—with inflammatory lesions near but not in joints. (Collins' more extensive data have since appeared.⁵²¹—Ed.)

TABLE II
Studies on Synovial Cytology (Collins²⁷³)

Condition	Cases studied	Total nucleated cells, per cu mm synovial fluid		Polymorphonuclear leukocytes, per cent	
		Usually	Range	Usually	Range
Normal		"About 200"		Below 10	
Atrophic arthritis	35	10,000-20,000	5,000-60,000	70-90	40-100
Hypertrophic arthritis	4	Below 1,000	Below 1,000-10,000	Below 10	0-20
Gonorrheal arthritis (sterile fluids)	4		5,000-30,000		30-80
Intermittent hydrops	1 (two samples)		1,600, 2,500		58, 78
"Sympathetic joint effusion"	2		Below 1,000		0-20

Warren, Bennett and Bauer⁵²² studied the synovial fluid at necropsy of 150 persons who had died of miscellaneous conditions and had had no joint symptoms. Synovial cytology may be unaltered, though the patient has a marked leukocytosis. Cartilage defects and débris may increase the nucleated cells and percentage of phagocytes. The total nucleated cell count per cu mm is reduced in synovial effusions in edematous patients. Patients dying with any severe infection (without joint symptoms) sometimes have a high, synovial total cell count and polymorphonuclear leukocytosis.

Leukocytes contain proteolytic (tryptic) ferments which, in sufficient amounts, can destroy articular cartilage. To prevent leukocytes in synovial fluid from doing this, synovial fluid contains antitryptic substances which inhibit tryptic digestion (Holmes, Keefer, Myers^{523, 524}). These antitryptic substances (which can be removed from synovial fluid by extraction with chloroform) probably come from blood plasma, as their concentrations in fluid and plasma are similar. Synovia cannot protect cartilage adequately when its antitryptic powers are reduced in the presence of effusions containing large numbers of cells, especially polymorphonuclears, for from such effusions, particularly purulent exudates, proteolytic enzymes are liberated in great amounts. (Hence the necessity of draining purulent or suspected purulent effusions promptly to prevent or minimize cartilage destruction—Ed.) Nevertheless, synovial fluid is apparently able to prevent or inhibit cartilage destruction even when the synovial fluid contains as many as 20,000 leukocytes per cu mm, for it was found that although cartilage destruction occurred *in vitro* in the presence of synovial fluid in two cases of staphylococcic arthritis in which synovial fluid cells numbered 110,000 to 240,000 per cu mm, car-

tilage destruction did not occur in the presence of synovia in seven cases of gonorrheal arthritis with 7,850 to 21,000 cells per cu mm of synovia, or in three cases of tuberculous arthritis with synovial counts of from 6,500 to 11,600 cells

To study healing processes in joints, Bennett and Bauer⁵⁻⁵ compared the processes of cartilage repair in adult dogs to those in young dogs in which epiphyseal union had not yet occurred. Defects of central, non-weight bearing articular cartilage were produced surgically. Repair of these defects was no more rapid or complete in young dogs than in adult dogs. In both, healing was slow: none was noted after four to 12 weeks, it was notably present but incomplete after 20 to 28 weeks. Repair occurred in three ways: (1) an independent proliferation of original cartilage cells, this was greater in the deeper zones of articular cartilage than in the more superficial zones, (2) proliferation of vascular tissue from perichondral margins, (3) when subchondral marrow spaces were involved in the surgical defect there was also an ingrowth of vascular connective tissue therefrom. Repair (active proliferation of cartilage cells) occurred most satisfactorily when the defect extended into subchondral bone (in which case granulation tissue from marrow spaces gradually filled the defect), or in crevices where cartilage was protected from friction. The latter would indicate that function may inhibit repair. Bennett and Bauer were unable to corroborate the opinion of Key (1931) that such defects in articular cartilage may be an important cause of intra-articular disease. Associated intra-articular disease was found only in joints where patellae became displaced.

Studies on the comparative value of four dyes used for the arthrographic diagnosis of joint mice, cysts, semilunar injury and so forth, were made by Keller^{62a}. For diagnostic purposes the ideal dye should produce sufficient opacity for roentgenographic detail, a minimum of discomfort and reaction after injection, and be eliminated rapidly enough to avoid irritation as a foreign substance but not too rapidly to prevent painstaking radiologic studies. All four dyes used produced satisfactory opacity, but hippuran gave the mildest post-injection reaction, a sense of fullness without pain, and it was therefore preferred. It disappeared from joints in three to four hours. After administration of arthrospin articular pain lasted a few hours (time unstated), after neoipax three to 10 days, after skiodan it was severe and lasted over two weeks. Some patients with "chronic arthritis" noted improvement in the injected joint after the post-injection reactions. Therefore if one wishes to attempt a therapeutic as well as diagnostic procedure, arthrospin was recommended. It disappears from normal joints in 17 to 24 hours, sooner from joints subacutely inflamed, much slower from joints with thickened capsules. Use of these dyes is presumably contraindicated for patients with liver or kidney disease or hyperthyroidism. Arthrospin contains 68 per cent iodine, and is a 10 per cent solution of the disodium salt of tetraiodo-ortho-sulpho-benzoate.

The Golgi apparatus appears as reticular material in almost every cell of all animals. Its nature is uncertain. Some consider it an artefact, but it has been observed in living cells. Others regard it as indicating an area of protoplasm which is the site of special activities. Whatever it is, this "apparatus" is a morphologic component of cells demonstrable in certain circumstances and altered by environmental changes that affect other parts of the cell only slightly or slowly. Thus when tissues are removed from the body the Golgi material disappears before there are any (other) visible autolytic changes. In mild degenerative conditions in which the blood supply is impaired or disintegrative changes are present in cells the Golgi apparatus is grossly altered or absent. Never noted previously, a well-developed Golgi apparatus comparable with that of other connective tissue cells was demonstrated by King⁵²⁷ in synovial tissues of humans, horses and dogs. The apparatus becomes enlarged in conditions with increased synovial fluid. Cells, including synovial cells, free in synovial fluid also show the apparatus. Since it is not demonstrable in degenerative states, its well-developed character in synovial cells indicated to King that synovia is not a product of degeneration as some contend. Since the Golgi bodies of synovial cells are enlarged in inflammatory conditions he suggested that the enlarged apparatuses indicate secretory activity of synovial cells. (A good review of synovial histology was given—Ed.)

Allen⁵²⁸ noted that non-particulate solutions (methylene blue and trypan blue) escaped from knee joints of live cats and appeared in iliac lymph nodes in one to four minutes, but that particulate matter (India ink, erythrocytes) did not appear in nodes for three to five hours. Experiments were then done on perfused kittens just after death. Muscular contraction, joint involvement and increased joint tension caused more rapid passage of fluid and particulate matter from joints to lymphatics. Certain bacteria were injected directly into joints and subsequent cultures of blood and lymph nodes were taken. Animals allowed to move around had a tendency to show more positive blood cultures than those whose joints were fixed in plaster. Allen interpreted these results as evidence that immobilization of infected joints is desirable to prevent spread of infection.

A method for measuring and recording joint function was reported by Cave and Roberts,⁵²⁹ and Moore⁵³⁰ described an apparatus for articulometry of feet.

CASE REPORTS

EXTRAPYRAMIDAL SYNDROME AND ENCEPHALOGRAPHIC PICTURE OF PROGRESSIVE INTERNAL HYDROCEPHALUS IN CHRONIC HYPOLYCEMIA

By ABRAM BLAU, M D , *New York, N Y* , NORMAN REIDER, M D , *Topeka, Kansas*, and MORRIS B BRNDER, M D , *New York, N Y*

IN the past decade since the description of the syndrome of spontaneous hypoglycemia or hyperinsulinism, numerous cases have been recognized and reported. The variegated symptom-complex has become more definitely delineated and a number of comprehensive reviews of the subject have appeared¹. The neuropsychiatric symptoms of hypoglycemia are among the most interesting, and have received special attention by Stone² and others.

The purpose of this communication is to record a case of chronic spontaneous hypoglycemia which has been studied over a period of 16 months of hospitalization. The outstanding features included convulsive seizures, hypoglycemia, and a persistent extrapyramidal syndrome with encephalographic evidence of progressive internal hydrocephalus.

CASE REPORT

History H L , a white male, aged 49 years, was admitted in a comatose condition to the Neurological Service of the Mount Sinai Hospital on February 16, 1934.

The familial and past history were essentially negative. He had followed various forms of employment, including that of a painter for a short period, until June 1933 when he began to suffer from weakness, tiredness, mental depression, and attacks of dizziness. One month later, he began to have periods of unconsciousness accompanied by abnormal movements and rigidities in the extremities. During these episodes his breathing became noisy and saliva drooled from his mouth. The entire attack lasted from one to three hours, recovery was spontaneous. On regaining consciousness he complained of headache and was unable to recall any of the preceding events. There was no aura, he did not cry out at any time, did not bite his tongue, nor was there incontinence. These episodes recurred at intervals of about a month, and were not noted to occur at any particular time of the day. During the eight months preceding his present admission his speech became slower and thicker, he seemed to have difficulties in articulation, his vision and hearing became impaired, and micturition became more frequent, without polydipsia. A change in his personality was noted by his friends and relatives, he became morose, depressed, asocial, preoccupied, disinterested in his surroundings and definitely detached from his former activities.

On two occasions he was admitted to the neurologic service of another institution (October 22 to November 14, 1933, and from January 12 to February 13, 1934), where a cerebral neoplasm was suspected, but no definite diagnosis could be made. An encephalogram on each admission showed mild cerebral atrophy but failed to show deformity or displacement of the ventricular system. Two blood sugar esti-

* Received for publication April 16, 1936.

mations were reported as 189 mg per cent and 42 mg per cent respectively. Other clinical and laboratory studies were essentially normal.

Examination showed a well developed and well nourished adult white male in a semi-stuporous condition. The systemic examination was essentially negative. The blood pressure was 140 systolic and 90 diastolic. The positive neurologic signs included hyperactive deep tendon reflexes which were more marked on the left, absent superficial reflexes, Hoffman reflex positive on the left and inconstant on the right, Babinski sign positive on the right and equivocal on the left, and a slight weakness of the left lower facial musculature. The pupils were equal and reacted promptly to light. The fundi oculi were normal. A lumbar puncture revealed clear fluid under a pressure of 120 mm of water. The Queckenstedt test was negative. After the removal of 10 cc of fluid the pressure dropped to 40 mm. The stupor persisted and irregular convulsive movements appeared. Fifty cc of 50 per cent dextrose were then administered intravenously, without effect. The convulsive movements and stupor continued for another three hours, when he gradually began to respond. The following morning (12 hours later) he was mentally clear.

The diagnoses considered on admission were brain tumor, presenile dementia (Alzheimer's disease), or subacute encephalitis. On April 2, 1934, to rule out a brain tumor, an encephalogram was performed, following which he became stuporous and showed a recurrence of the convulsive semi-purposeful movements. A blood sugar estimation at this time was 45 mg per cent. Following the intravenous administration of 70 cc of 50 per cent glucose, he regained consciousness, responded to questions and began to complain of headache. The diagnosis of hypoglycemia became probable and was confirmed by the subsequent course.

The course and data are best presented under separate headings.

(a) *Hypoglycemic Seizures*. The hypoglycemic seizures were the outstanding manifestations of the illness. During a period of 14 months, 130 seizures were observed (table 1). The seizures occurred at all times of the day, but a majority were in the afternoon.

TABLE I

The distribution and frequency of the attacks are tabulated. During July, the patient was receiving foreign protein fever therapy. The lower part of the table shows the greater frequency of the attacks during the afternoon.

<i>Month</i>	<i>Number of Attacks</i>
April 1934	7
May	19

<i>Period of Day</i>	<i>Number of Attacks</i>
12 m to 6 a m	10
6 a m to 12 Noon	18
Noon to 6 p m	77
6 p m to 12 Noon	25

A seizure was preceded by apprehensiveness and irritability, the patient expressed ideas of hopelessness, said that he was going to die and became very uncooperative. He then became drowsy and stupor gradually supervened. The breathing became stertorous and noisy and bizarre convulsive movements set in. The movements were clonic and had a semi-purposeful character: these were groping of the hands, thrashing of the arms, treading motions of the legs, and turning movements of the body. The movements were irregular, involving either the whole body, one side, or even single limbs, but at no time was there a cortical spread of the seizure. The eyes were closed and the mouth drooped, and sometimes the head would roll from side to side. There were no clonic movements of the jaw, or biting of the tongue or lips. There was a marked increase of salivation but as a rule no frothing at the mouth. As the attack continued considerable amounts of saliva would drool from the mouth, and on one occasion 250 c.c. of saliva were collected within a period of one and one-half hours. Unconsciousness was complete, but the pupils continued to react to light. The tendon reflexes were usually hyperactive and occasionally showed some inequality. A Babinski sign was frequently elicited, but this was inconstant and varied from side to side.

At times, particularly in the later period of observation, "minor" attacks without convulsive movements would occur. These were characterized by lapses in which he would become drowsy, restless, and would assume a vacant expression and blink his eyelids. His responses were automatic, and no mental contact could be made. These attacks would last from a few minutes to one-half hour.

If not ended by an intravenous injection of glucose, the "major" attacks continued for two to three hours. He would then recover spontaneously without the ingestion or injection of any nutriment. Following these spells he was completely amnesic for the events occurring during or immediately preceding the seizure. The attack could always be aborted immediately by the intravenous injection of dextrose. He was usually given 50 c.c. of 50 per cent dextrose intravenously, but relief could be obtained with as little as 5 c.c. of 50 per cent dextrose. Figure 1 C shows the effect on the blood sugar of intravenous glucose administered to relieve two hypoglycemic seizures. Normal saline intravenously in similar amounts had no effect. Sweetened orange juice by mouth usually prevented an attack when given at the time when restlessness appeared, but administered through a stomach tube when the patient was unconscious, caused but little response. Hypodermoclysis or proctoclysis of 5 per cent glucose was no more effective than glucose by mouth. Epinephrine (1 c.c.), pituitrin (1 c.c.), and Collip's diabetogenic pituitary extract,*³ as well as many other glandular preparations were ineffective in relieving an attack.

Blood sugar estimations (total reducing substance) during seizures were as low as 30 mg. per cent. However, a low blood sugar was not invariably associated with a hypoglycemic attack. The correlation between the blood sugar and the condition of the patient is shown by figures 1 A, B and C.

During the hypoglycemic seizure the blood pressure usually increased slightly but at times decreased, the secretion of saliva increased, the ocular tension (by quantitative measure) decreased, and the blood cholesterol was decreased. The electrocardiogram showed minor changes as inversion of the T_1 and T_2 waves, and sinus tachycardia.

An attack could not be precipitated by 10 units of insulin administered subcutaneously about one hour after recovery from a seizure. Induced alkalosis by hyperpnea for three minutes was followed by a long period of apnea but no other changes. An attack was invariably induced by starving, particularly by eliminating

* This extract, which will raise the blood sugar in a Houssay dog, was kindly furnished expressly for clinical trial on this patient by Dr J. B. Collip of McGill University, Montreal, Canada.

breakfast, and often by the omission of the sweetened orange juice which he was taking every two hours

(b) *Neuropsychiatric Symptomatology* The course was marked by the progressive and permanent establishment of extrapyramidal and cortical signs. His stance became stooped slouching, and more and more like that of a Parkinsonian. The gait was slow and stiff with a gradual diminution and finally a complete loss of associative movements of the arms. He later showed repulsive tendencies. His hands became tremulous and a perioral tremor developed. The tremor of the fingers

Fig 1 A

Fig 1 B

Fig 1 C

FIG 1 A, B AND C Graphs of blood sugar values estimated at frequent intervals throughout the day. There was no strict parallelism between the blood sugar values and the symptoms of hypoglycemia. Intravenous glucose was followed by a sharp rise and fall of the blood sugar.

was coarse and arrhythmic. On the finger to nose test he showed a slight intention tremor. Bilateral adiadochokinesis was noted early in his course. From day to day the speech became more and more dysarthric, thick, slow, syllabic, whining and, especially preceding an attack, was unintelligible.

The cranial nerves, except for hearing, were not involved. The fundi showed no changes, and repeated visual field examinations were normal. Visual acuity was O D 20/30, O S 20/70. The pupils were equal, regular and reacted well to light and accommodation. No weakness of the external ocular muscles was noted. Two months after admission, the patient complained of impaired hearing in the right ear, and this progressed to involve both sides. The hearing defect was found to be of the nerve type. The levels of both the upper and lower tones were markedly diminished, the upper tones being more involved. The deafness was more marked in the right ear. Immediately preceding discharge from the hospital he could not hear the tick of a watch placed 1 cm from the ear, when it was heard by the examiner at two feet, when placed against the ear, it was audible. Vestibular function as tested by the response to caloric (cold) stimulation, was normal.

The motor power became progressively weaker. The muscles showed increased myotatic irritability. During several hypoglycemic attacks coarse fibrillations were noted in the right forearm. The tendon reflexes were generally hyperactive, and showed inconsistent variations from day to day. Definite pathological reflexes, as the Babinski sign and other confirmatories were noted from time to time varying from side to side, but these were not persistent.

Sensation was not affected except for a short period four months after admission. At that time he began to complain of paresthesias in his hands and feet, and these gradually involved the forearms and legs. On examination he showed sensory diminution of all modalities in typical glove and stocking distribution. Within three months these signs and symptoms disappeared spontaneously. Apparently there was a transient attack of symmetrical peripheral neuritis.

The *mental condition* was one of progressive intellectual and emotional deterioration. He was completely amnesic regarding the seizures and on recovery from each often showed a short period of confusion. For two weeks in the early period of his observation he showed delusions of persecution and ideas of reference. He thought that the nurse wanted to poison him, that people were taking pictures of him, and he openly accused a number of other patients on the ward. He did not elaborate on these ideas and was irritable and belligerent. He later regained partial insight and reluctantly admitted that it was a product of his imagination.

His interests were minimal and gradually became fewer. He was content to sit by himself, and made few contacts with the other patients. He soon became incapable of coherent speech and his verbal productions were limited to a few requests regarding his immediate needs. When conversation was attempted he used few words and was often simply monosyllabic. When clear he was cognizant of his illness. He knew that he had low blood sugar and frequently reminded the nurses that his orange juice was due. He realized that he was permanently handicapped and that he would be unable to earn a living so that his general attitude was pessimistic, although he frequently appeared euphoric. At times he was facetious in a simple way and smiled even in irrelevant situations. At other times he became depressed emotionally unstable, and expressed fears that he would never be healthy. As previously stated an hypoglycemic attack was preceded by anxiety, apprehensiveness and irritability. His intellectual capacities showed progressive diminution. His memory became impaired both for recent and remote events. As a rule he had good insight into his somatic condition but not regarding his mental defects. His judgment was impaired.

(c) *Systemic and Laboratory* The systemic examination showed no unusual changes except for an increase in weight. On admission he weighed 152 pounds and a year later he had gained 21 pounds. The blood pressure varied from 130 mm of Hg systolic and 90 diastolic to 160 systolic and 100 diastolic. The numerous laboratory investigations showed very little of significance except those referable to sugar metabolism. The urine was normal and never showed any sugar. Special tests for lead in the urine were negative. The hematologic examination was normal. The cerebrospinal fluid sugar was 15 mg per cent. The blood cholesterol during an attack was decreased to 105 mg per cent. The Rehfuess gastric analysis showed a good acid curve with levels of total acid of 58 and of free HCl of 42, no blood or other abnormalities were noted. The stools were normal. The galactose tolerance test for liver function was normal and no sugar was excreted in the urine. Glycogen storage was deficient as there was no notable increase in blood sugar to epinephrine. The basal metabolic rate was plus 6 per cent. An electrocardiogram showed regular sinus rhythm, left ventricular predominance, and an inverted T_2 wave. During an attack the electrocardiogram showed sinus tachycardia and inverted T_1 and T_2 waves. The roentgen-ray of the skull, and a gastrointestinal series were negative.

(d) *Blood Sugar* The Folin-Wu method modified for the estimation of low values was used for the venous blood sugar determinations. The fasting blood sugar

varied from 30 to 45 mg per cent. On two occasions, when allowance was made for the non-glucose reducing substances in the blood (estimation following yeast fermentation of glucose as compared to a non-fermented specimen), the fasting sugar values were 5 and 7 mg per cent respectively. These low sugar values as previously stated were not invariably associated with hypoglycemic seizures.

The Janney sugar tolerance test was performed 10 times during the period of observation (figure 2). As shown in the graph, the blood sugar level continued to rise for the first hour, rested at this level for about one hour, and then dropped to a point lower than the original fasting level. During the plateau-like period of high blood sugar value, a trace to 14 per cent sugar was noted in the urine on several occasions. Figure 1 *A* and *B* illustrate the diurnal course of the blood sugar while on a regular diet with additional glucose in the form of orange juice. Note that the values of blood sugar decrease in spite of the ingestion of food. Epinephrine and

FIG 2 Blood sugar tolerance curve (from average values of ten tests)

antuitrin tolerance tests demonstrated no significant alteration of the fasting blood sugar curves.

(c) *Encephalogram* Several encephalographic studies were carried out and these showed progressive cerebral pathology. The first encephalogram (figure 3) on April 2, 1934 was reported as "Both lateral ventricles symmetrical, moderately dilated and in the midline. In the posterior horn there is a shadow which protrudes into the ventricular region which I believe is not pathological. The third ventricle is dilated and in the midline. The iter and fourth ventricle are also slightly dilated. The basilar cisternae are somewhat enlarged, and on some of the films there is evidence of air in the subtentorial region. Subarachnoid markings are not evident." This encephalogram was essentially similar to two others obtained previously one and four months respectively at the other institution. The encephalogram was repeated on March 29, 1935, and the principal change was an increase in the size of the ventricles (figure 4) indicating *progressive internal hydrocephalus*.

(f) *Treatment* Both as a diagnostic and therapeutic measure, an exploratory laparotomy was performed on May 12, 1934, by Dr A. A. Berg. The pancreas,

adrenals and liver were examined and were found to be normal. Biopsy specimens were removed from the liver and pancreas, and histological examination showed no unusual features.

A great variety of other therapeutic measures was investigated. Since none of these seemed to have any appreciable effect on his condition, they are only mentioned.

Fig 3 A

Fig 3 B

FIG 3 A AND B Encephalogram on April 2, 1934, showing internal hydrocephalus

Fig 4 A

Fig 4 B

FIG 4 A AND B Encephalogram on March 29, 1935, showing increase of internal hydrocephalus

These medicinal agents included pituitrin (grains II, twice daily), whole pituitary gland extract, thyroid extract (grains $\frac{1}{2}$, three times daily), Collip's diabetogenic pituitary extract, MacCallum-Laughton's duodenal extract, acetylcholine, and atropine. The injection of atropine, however, seemed to produce a violent attack which was difficult to control even with intravenous glucose.

The patient received two courses of non-specific foreign (typhoid vaccine) protein therapy. During the first series, which was given soon after admission, his seizures were arrested for a short period, and for this reason it was thought advisable to repeat this procedure. However, the second course of treatment had little effect on his general condition or blood sugar and did reduce the number of seizures. Blood sugar estimations before, during, and after a chill showed no changes.

Dietary measures were also discouraging. Controlled high and low carbohydrate diets with and without insulin were given a trial. The optimum conditions seemed to exist when he was allowed to eat a regular ward diet, supported at first by occasional and later by regular drinks of sweetened orange juice between meals, particularly when an oncoming attack was expected. For one month an attempt was made to induce ketosis with a ketogenic diet on the presumption that this would stimulate glycolysis; cooperation could be obtained for a high fat ketogenic diet of not more than 1:3 ratio. However, acetone was never obtained in the urine and the condition was unaffected.

As a final measure a two month course of deep roentgen-ray therapy directed to the pancreas was administered. A total of 1500 r were directed in each of two fields without any alteration of the blood sugar or the other symptoms.

(g) *Discharge and Follow-Up* The patient was discharged and transferred to the Montefiore Hospital for convalescent care on April 4, 1935. His course (to March 1936) at this institution has shown no marked changes except that his obesity has increased, the neurological picture has persisted.

COMMENT

The symptoms and signs in this patient were almost entirely neuropsychiatric and included changes in the central, peripheral and vegetative nervous systems as well as in the psyche. Such disturbances are characteristic of most cases of hypoglycemia. The most prominent and constant neurologic manifestations in the case were those referable to diseased striatocerebellar pathways. Throughout the period of observation the patient presented a typical Parkinsonian syndrome, which was progressive in nature, and therefore suggested a primary disease of the basal ganglia. Other significant neurologic changes included a transient attack of peripheral polyneuritis, progressive bilateral nerve deafness, emotional and intellectual deterioration, and progressive internal hydrocephalus.

The diagnosis was complicated by a number of unusual features. The clinical history was not suggestive of hypoglycemia since there was no noticeable relation between the symptoms and the intake of food, the attacks had occurred at any period during the day and despite the ingestion of meals. It is significant that the condition was considered as a neurologic problem in two hospitals. On admission, when the patient was in stupor an intravenous injection of glucose yielded no improvement. Recovery following the intravenous administration of glucose was not noted until about four months after admission. It is therefore evident why the hypoglycemia was not recognized, or even suspected on admission. A similar observation has been reported by Ferner, Soltz, and Haun⁴ in a verified case of adenoma of the pancreas. This observation is difficult to explain.

The fasting venous blood sugar estimations were remarkably low as compared to other reported cases. The general level of the reducing substances varied from 30 to 45 mg per cent and when allowance was made for other reducing substances the least fermentable sugar was estimated as low as 5 mg per cent.

It was also found that there was no strict parallelism between the level of the blood sugar and the severity of the symptoms (figure 1). At certain times the blood sugar values were low without attacks, whereas at other times when the levels were higher convulsions were present. Too, most of the seizures occurred in the afternoons (table 1) despite the fact that the patient ate his lunch. It is possible that the ingestion of food may have overstimulated insulin formation. The ingestion of food did not prevent symptoms of hypoglycemia, a fact contrary to most reports. Most observers state that the intake of food, especially in the form of sweetened orange juice prevents or checks the hypoglycemic attack almost immediately. In our case no method except the intravenous administration of glucose was successful. Even small amounts of glucose by this channel were effective. Glucose by mouth, by rectum or subcutaneously was without result. The effect of fever therapy in this case merits additional reference. During the first course of foreign protein therapy, the patient showed remarkable improvement and convulsive seizures did not occur. At a later period, however, the repetition of this treatment was less effective, in that the hypoglycemic attacks diminished in number but did not disappear entirely as previously. Moreover, blood sugar estimations at this time showed no change, the fasting and other sugar values were the same as on days prior to the institution of foreign protein therapy. Theoretically, if the condition of our patient may be considered as one of hyperinsulinism, the fever therapy may have been effective in reducing the activity of the endogenous insulin. The occurrence of this phenomenon is well known in febrile diabetic patients in whom it is found necessary to increase the maintenance doses of exogenous insulin.

This is probably the first case of hypoglycemia in which progressive internal hydrocephalus has been demonstrated by encephalography. The exact significance of this change must await pathological studies. Other noteworthy alterations during the hypoglycemic seizure were increased salivation, changes in the T-waves of the electrocardiogram, a decrease of blood cholesterol, and a reduction of ocular tension. The latter finding is similarly found in the quite contrary condition of diabetic coma.

The etiology of the hypoglycemia in our case is not clear. Some authors attach importance to the pituitary gland as a causative factor, but the evidence for such an hypothesis is not well established. The only endocrine disturbances manifested in our patient were increase in weight and development of greasiness of the face, and these may be due to disease in the vegetative nervous system. The obesity was probably due to an increase in the caloric intake from the sweetened orange juice given every two hours in order to avoid the hypoglycemic attacks. Diseases of the pancreas, liver and adrenals as the cause of hypoglycemia were probably excluded by exploratory laparotomy and biopsy. However, biopsy of normal tissue from one part of the pancreas or liver, or palpation of the adrenals does not necessarily exclude pathologic lesions in other parts of the explored organs. Furthermore one may also be reminded that it is possible to have abnormal function in the presence of normal morphology. In the final analysis altered function is more significant than altered structure. Numerous instances have been cited where individuals were suffering with hypoglycemia of unknown etiology. These cases are designated as idiopathic, and in most instances the pancreas has been explored and found to be negative.

Finally in our patient, the persistence of the extrapyramidal syndrome raised the question whether the disease of the periventricular nuclei caused both the abnormal movements as well as the hypoglycemia. Theoretically it is possible that disturbances in the sugar metabolism may occur from disease of the glucose regulating center in the brain. As a matter of fact, a case of acute lethargic encephalitis associated with disturbances in sugar metabolism and vegetative functions was recently observed by us. The course, however, in this case was acute and brief, and the disturbances were transient. In the patient with "chronic hypoglycemia" the symptoms and signs of basal ganglia disease were insidious in onset and persistent. From these observations one may infer that disease of the vegetative centers may produce chronic hypoglycemia. On the other hand, one may argue that a persistent hypoglycemia, whatever the cause may be, may produce permanent damage to the brain and therefore produce manifestations of disturbed nerve function. Recent experiments performed on rabbits revealed that convulsions caused by hypoglycemia produced definite anatomic changes in the central nervous system, and the greater the number and the more prolonged the convulsions, the more severe were the lesions.⁵ Our patient had numerous convulsions and encephalograms taken a few months apart revealed a progressive internal hydrocephalus. It is possible that the changes in the brain in this case were caused by the repeated convulsive seizures. On the other hand, it may be claimed that the internal hydrocephalus was the result of primary disease of the brain and that the hypoglycemia which caused the convulsions was secondary.

We are unable to conclude as to which theory is correct. In any case there seems to be a definite relation between disease of the periventricular nuclei and glucose metabolism.

SUMMARY

- 1 A detailed case history of chronic hypoglycemia is described.
- 2 The outstanding features were a persistent Parkinsonian syndrome and evidence of a progressive internal hydrocephalus as shown by several encephalograms.
- 3 Attention is called to the coexistence of manifestations of chronic disease of the periventricular nuclei and the constant hypoglycemic state. The relation between these two is discussed from the standpoint of etiology, but no definite conclusions are drawn.

UVEO-PAROTID FEVER, WITH CASE REPORT

By HERMAN R. PARKER, M.D., *Greensboro, North Carolina*

UVEO-PAROTID fever or Heerfoidt's disease, is a comparatively rare affection characterized by (1) an iridocyclitis, (2) a bilateral almost painless swelling of the parotid glands, (3) a low grade chronic fever running a course of from several weeks to two or three years and subject to considerable variations, and (4) by the occurrence of irregular constitutional symptoms. The syndrome may occur at any age but is most common in the second and third decades, and is slightly more prevalent in females.

Of frequent, though not constant, occurrence are (1) a prodromal stage, lasting for several weeks or months of general malaise and drowsiness with a tendency to frequent gastrointestinal upsets and abdominal pains, (2) paresthesias and polyneuritis, (3) paralysis of the cranial nerves particularly the seventh, (4) a rash resembling erythema nodosum occurring chiefly on the extensor surfaces of the forearms and legs and extending slightly above the knees and elbows, (5) a polyarthritides, (6) swelling of the cervical lymph nodes and the submaxillary and lacrimal glands, (7) a polyuria without glycosuria, and (8) a long continued dryness of the mouth.

The eye symptoms are quite variable. They may include misty vision with more or less impairment of sight, narrowing of the palpebral fissures, ciliary congestion, sluggish and often irregular or dilated pupils with little or no response to light or accommodation, vitreous opacities, optic neuritis or atrophy, iritis, keratitis, cataract, and glaucoma.

The parotid swellings are usually bilateral and painless. They may be hard or nodular and limited to the pre-auricular area or much more extensive involving all of the salivary tissue. This engorgement usually lasts several weeks or months, but the glands never suppurate.

There seem to be great variations in the order of the appearance and in the severity and duration of symptoms, but the similarity in cases thus far reported unquestionably justifies the classification of a separate clinical entity.

CASE REPORT

History of Present Illness. The patient, a white female, aged 33, was seen by me at her home late in the night of February 14, 1935 for a severe headache and pain in and over the eyes. She also complained of a slight sore throat and aching of the entire body which had begun four or five days previously. The temperature was 102.5° F, and the pulse 110, otherwise the examination was essentially negative. Her suffering was apparently so intense that I administered morphine gr 1/2, hypodermically, which soon gave fair relief. During the next two or three days I received reports to the effect that she was much improved, being able to keep fairly comfortable by the use of aspirin alone. On the eighteenth I was called to see her again, and found that in addition to an exacerbation of the initial symptoms, a distinct redness of the conjunctivae and a photophobia had developed. Two or three days later the patient complained of a blurred or misty vision and of not being able to distinguish objects in the room unless they were brought very close up. Also, she complained of an intense dryness and stickiness of the mouth. At this time there was noticed some degree of swelling on both sides of the face in the regions of the

* Received for publication January 20, 1936

parotid glands This swelling was not painful, but was slightly tender on pressure The posterior cervical glands were also enlarged and slightly tender Within the next two days there developed some edema of the upper lids, and the photophobia was more pronounced, also, the pupils were dilated and reacted very poorly to light The temperature continued to range from 100° F to 102° F, and the patient became quite drowsy, being disturbed at intervals with pains about the head During the next few days the swelling of the parotids increased, the eyes became swollen completely closed, and the mental state varied from an intense drowsiness or lethargy to a wandering hallucinatory delirium On February 23 and 24 an eruption appeared on the extremities, extending from approximately the middle of the arms and thighs down to and including the hands and feet, but most pronounced on the forearms and legs and involving chiefly the extensor surfaces The lesions consisted of discrete, ecchymotic, subcuticular nodules, varying in size from about $\frac{1}{4}$ cm to $1\frac{1}{2}$ cm in diameter Two days later, or 16 days from the initial onset of symptoms, the patient was admitted to the Wesley Long Hospital

Family History A husband and two children, ages 12 and 6 years, are living and well Both children, however, were sick for several days with "colds" a week or two before the onset of the patient's present acute illness Neither of her children has had mumps, nor has there been any illness in the home since the patient's attack suggesting contagion Six years ago her husband's sister who had active pulmonary tuberculosis visited in the home for two weeks Otherwise the family history is negative

Personal History The patient sleeps fairly well, her appetite is good, there is no constipation or apparent inability to digest foods Her maximum weight was 145 lbs three years ago, present weight is 137 lbs Menstruation began at the age of 15 and was regular and normal until after the second child was born six years ago Since then it has occurred at five to seven week intervals, the flow is scant and lasts only two or three days There have been two normal pregnancies and no miscarriages

Past History She had measles, mumps, whooping cough, and German measles as a child Her tonsils were removed about 10 years ago Eight years ago she had an operation at which the appendix and one ovary were removed and the gall-bladder drained Six years ago, and about four or five months after the sister-in-law with tuberculosis visited in the home, the patient developed a pleurisy of the left side which lasted several weeks, but has never recurred Moreover, she has had two roentgen-ray studies of the chest since which did not reveal evidence of tuberculosis About two and a half years ago the patient began having headaches, chiefly occipital, and after having her glasses changed several times the headaches improved She also complained of a general malaise, weakness and fatigue Shortly after this she began having attacks of stiffness in the wrists, shoulders, and neck, especially following exposure to drafts at night Soon there developed pains in the chest and lower abdomen, and pains and stiffness in the lower part of the back, in the hips, legs, arms, and joints—especially of the wrists, hands, and ankles Also, she was found to be running a slight fever

On July 16, 1933, the patient called at my office complaining of swollen glands about the neck, and stated that the condition had been developing for a week Her temperature was 102° F, the cervical lymph nodes, both anterior and posterior, were greatly enlarged, and there was slight enlargement of the epitrochlears She was confined to bed for four weeks during which the glandular enlargement gradually diminished without suppurating, but the glands remained definitely larger than normal Also, the temperature ranged lower, but continued to run from normal to 100° F Undulant fever was considered, and upon inquiry it was elicited that a cow from which the family used milk had recently aborted Blood was taken two weeks from the onset of this attack, and again one week later, for agglutination

against *Brucella*, both, however, were negative. The blood Wassermann was negative, and an intradermal tuberculin test was positive. A leukocyte count at this time was 4,500 with a normal differential. Two weeks later the patient was referred to an otolaryngologist who was unable to find any evidence of disease in the throat and sinuses. She was then referred to a dentist who found several diseased teeth which were extracted over a period of several months. The following October (1933) she was admitted to Duke Hospital (Durham) where a very complete study of her condition was made. A summary of their significant findings are as follows: Enlarged cervical and epitrochlear lymph nodes, temperature 100° F, pulse 126, slight tenderness in the sacro-iliac joints, lower abdominal quadrants, and right adnexal region of the pelvis, a negative agglutination test for undulant fever, a positive tuberculin test, a low glucose tolerance (209 mg per cent at 15 hours, and 130 mg per cent at three hours), and a metabolic rate of minus 2 per cent. No diagnosis was made, but an impression of the presence of neurasthenia and, possibly, of a tuberculous infection of the Fallopian tubes was offered. Her course continued practically unchanged for approximately the next 18 months, or until the acute condition herein described developed in February 1935, when she was admitted to the Wesley Long Hospital.

On admission to the hospital the temperature was 101° F, pulse 100, and respirations 22. The heart, lungs, abdomen, and reflexes were apparently normal. In fact, with the exception of the symptoms above described, the physical examination was essentially negative.

Laboratory Findings. Urine. An occasional red blood cell and a few pus cells were found on one occasion, otherwise, negative. Blood. Erythrocytes, 3,420,000, hemoglobin (Sahli), 78 per cent, leukocytes, 16,500 with 82 per cent polymorphonuclears, 14 per cent small lymphocytes, 3 per cent large lymphocytes, and 1 per cent eosinophiles, blood platelets, 258,400, coagulation time, 4½ minutes, bleeding time, 1 min 40 sec. Two blood cultures were negative after five days' incubation, and a culture of material aspirated from several of the subcutaneous nodules was contaminated. Roentgen-ray (Dr E. D. Apple). "Stereo films were made of all sinuses. Both ethmoidoids show cloudiness involving all of the cells, the cell outlines, however, are not completely obscured. The sphenoids also appear slightly clouded. Both antra show evidence of thickened lining membrane, they do not contain fluid. The left frontal is very small and shallow. The right is larger, though still small. They both appear clear."

On the same day of admission Dr. Frank Sharpe saw this patient in consultation with me, and the following day I had Dr. E. Prefontaine (ophthalmologist) see her and take over the care of the head condition. A report of his findings and conclusions is as follows: "The patient was very drowsy. She complained of a marked photophobia and dimness of vision which had existed for about two weeks. There was a fullness of the neck and face similar to that present in mumps, a marked edema and redness of both upper lids, and a skin rash on the forearms and legs. Closer observation revealed the following: chemosis of the conjunctivae, generalized, but most marked on the temporal sides of the corneas, no evident pericorneal injection or corneal deposits, iris clear, but reacting sluggishly to light, and ocular movements normal in all fields. Intra-ocular examination—difficult on account of ptosis and photophobia—revealed media clear and eye grounds normal. No visual test was made. Examination of the nose and para-nasal sinuses revealed a marked bilateral edema and irritation of the nasal mucosa, and a purulent secretion in both nostrils. On transillumination both antra and frontals were moderately dark. The pharynx was dry and granular. There were hard nodular swellings in the regions of both parotids. The sublingual and submaxillary glands were apparently normal. After four days the edema of the lids began to disappear from the nasal side. Chemosis now being localized to the upper temporal region, the edematous lacrimal glands

could be definitely palpated, and, on retracting the upper lids, were visible. Conclusions: Acute ethmoiditis, acute parotitis, acute dacryoadenitis. Also, in considering the history of photophobia and dim vision which were most marked before the patient's admission to the hospital, it is most probable that some ciliary irritation or some neuro-retinitis had existed in spite of the absence of positive findings at the time of examination." Briefly, within three or four days following admission the symptoms began to abate, and after a stay of 11 days she left the hospital much improved and fairly comfortable. It was noticed, however, from the nurses' records that while in the hospital she voided from one to three times every night between 8 p.m. and 6 a.m.

Two weeks after leaving the hospital another examination by the ophthalmologist revealed that the vision had returned to normal, and that there were no synechiae or corneal deposits, or any evidence of optic neuritis or atrophy, also, the nasal condition had entirely cleared up. At this time the rash on the limbs, the swelling of the parotids, and the edema of the orbital tissues had practically disappeared, but there persisted for at least two months a very noticeable narrowing of the palpebral fissures. Also, during this time the patient ran a slight fever almost continually. It seldom rose above 100° F., and seemed to manifest no daily regularity, being highest in the morning about as often as in the afternoon or evening. In addition she suffered frequent attacks of severe abdominal pains, and the neuritis and joint and muscle pains continued to be quite annoying, moreover, the nocturia continued with a frequency of from one to five times every night. After about five months, or during the month of July, all of these symptoms began to abate, and by November had almost entirely disappeared. The fever first began to intermit daily, then at longer intervals, and later was seldom found above normal. Another examination of her chest, including a roentgen-ray study, was made at The Guilford County Tuberculosis Sanatorium on June 20, 1935, by Dr. M. D. Bonner who reported no evidence of tuberculosis. By late 1935 her weight was 137 lbs., the hemoglobin (Sahli) 76 per cent, and the cell counts normal. A number of urine examinations, including two cultures for tubercle bacilli, have been made with only normal findings. Also, another agglutination test for undulant fever was negative. It seems that in spite of this prolonged illness with fever, the patient has maintained her weight and energies remarkably well, and the blood picture has remained practically normal. Incidentally, it may be of interest to note that she became pregnant in July 1935, her last pregnancy having been more than six years before, and she denies having ever used contraceptive precautions.*

DISCUSSION

Heerfordt,¹ whose name the disease now bears, was the first to recognize and describe this syndrome. In 1909 he reported three cases observed by him in the city hospital at Copenhagen, and discussed two others with similar symptoms from the literature,—one reported by Daireaux and Pechin in 1899, and the other by Collomb in 1903. Merrill and Oaks,² in reporting a case in 1931, reviewed the literature up to that date and tabulated an analysis of 29 previously recorded cases. Later Garland and Thompson³ gave a still more comprehensive review of the subject, and, more recently, Savin⁴ has presented a most excellent analysis of 66 published cases and added one of his own. Reports of at least seven others⁵ have appeared since Savin's publication, making a total of approximately 74 recorded cases. It is interesting to note that most of the existing

* Since this article was submitted for publication the patient's pregnancy progressed normally to full term. The patient had a normal labor and delivery in February 1936, and in September 1936, reported herself free from fever and in good health.

reports have come from Scandinavia, Germany, and Great Britain, while only six have appeared in American literature. The condition is probably more common than is usually suspected, but is rare enough not to be readily recognized.

Etiology The question of etiology in this disease is very much in controversy, moreover, there is a great diversity of opinion among the authors of reported cases concerning this point. Heerfordt¹ thought his cases were atypical mumps. Fuchs⁶ was of the opinion that uveo-parotid fever could not be definitely separated from Mikulicz's disease, and Hamburger and Schaffer⁷ thought it was a variety of the Mikulicz syndrome. Mohr⁸ ascribed the lesions to syphilis. Viner,⁹ Adams,¹⁰ and MacKay¹¹ thought infections of the mouth were responsible for the condition. Ramsay¹² classed it as a deficiency disease. Parker¹³ considered it to be an infective multiple neuritis with lesions in other tissues (parotid, uvea, skin, etc.). Schall,¹⁴ Garland and Thompson,³ Ulthoff,¹⁵ Roenne,¹⁶ Gjessing,¹⁷ Cavara,¹⁸ and others think the condition is caused by tuberculosis of a particularly fibrosing and noncaseating type—and there is considerable, though not altogether incontrovertible, evidence in support of this view. In fact, microscopically, the histological reactions of the tissues involved are apparently identical with those produced by tuberculosis. Moreover, McCurry¹⁹ actually demonstrated the tubercle bacilli in biopsy sections from both parotid glands of a patient (case 2) presenting the uveo-parotid syndrome. And, of the five patients who have died, tuberculosis was demonstrated in four at autopsy, the fifth was not examined. At least, in the cases thus far reported, there has been an exceedingly high incidence of associated tuberculosis, suggesting very strongly a probable etiologic relationship. Merrill and Oaks² attribute this disease to a "specific virus or bacterium as yet undetermined", while Cohen and Rabinowitz⁵ think it is an infective-allergic condition caused by "an organism, as yet not isolated, which produces a low grade infection in a sensitized individual". In the opinion of the author, the weight of evidence, both from reported cases and from the clinical course and picture of the case observed, suggests very strongly that the condition is rheumatic in nature—thus, its protean manifestations.

AMEBIC ABSCESS OF THE LIVER, REPORT OF A CASE WITHOUT PREVIOUS MANIFESTATIONS OF AMEBIASIS, OPERATION AND RECOVERY *

By HAROLD L GOLDBURGH, M D, *Philadelphia, Pennsylvania*

VARIOUS authorities differ as to the prevalence of amebiasis in countries other than the tropical regions. It is claimed that it occurs in the temperate climate more frequently than is generally believed. Craig's¹ opinion that between 5 and 10 per cent of the American population harbor this infestation is based on his collected statistics of 49,336 persons examined, 11.6 per cent having been found positively infected. Sir Leonard Rogers,² quoting C. Dobell, stated that between 7 and 10 per cent of the people of North England were carriers of the *Endameba histolytica* during the Great War. In 1934 Wenrich, Stabler and Annett,³ of the University of Pennsylvania, examined 1,060 freshmen students at a professional school in Philadelphia and found that 4.1 per cent harbored the *Endameba histolytica*.

In Philadelphia prior to the Chicago epidemic of 1933 amebiasis was a sporadic disease. Between January 1926 and November 1935, among 232,100 admissions to the Philadelphia General Hospital, there was one proved case of amebic dysentery, admitted in September 1930 to the service of Dr. Russel Boles. At the Jefferson Hospital during the same period, among approximately 120,000

* Read before the Section on General Medicine of the College of Physicians of Philadelphia, January 27, 1936.

From the service of Dr. Samuel A. Lowenberg, Philadelphia General Hospital.

admissions, there were six cases of amebic dysentery. All followed the Chicago epidemic, three occurring in the latter part of 1933 and three in 1934. Up to November 1935 the Bureau of Health of Philadelphia⁴ had recorded 43 cases of proved amebiasis all of which had likewise occurred subsequent to August 1933 when the segregation of the dysentery cases was first started.

The most frequent complication of amebiasis and amebic dysentery is abscess of the liver. It is frequently undiagnosed before death especially in temperate climates where amebic infection, until recently, was little understood and was

FIG 1 *Endameba histolytica* Vegetative form discovered in the abscess cavity $\times 2024$

regarded by most of the profession as a tropical disease. Ochsner and Bakey⁵ have reported on 4,484 cases of amebic abscess of the liver collected from the literature. According to some investigators amebic abscess of the liver is observed in from 2 to 20 per cent of those infected but living and in from 15 to 59 per cent of the autopsied cases of this disease. Brown⁶ reported 22 cases of hepatic involvement from the records of 834 cases of amebiasis at the Mayo Clinic. Of these 16 were proved cases of hepatic abscess, approximating 2 per cent.

At the Philadelphia General Hospital during the last 10 years, among the 232 100 admissions and 24,000 autopsies, there were five cases of proved amebic abscess of the liver. Three cases were diagnosed clinically. The first was operated on by the late Dr Hiram Loux in 1925. The second was the case which is the subject of this report, occurring in October 1935. The third was admitted later in 1935 and was operated on by Dr Mitchel P Warmuth. The remaining two were diagnosed at autopsy. At the Jefferson Hospital during the last 10 years there has been but one case of clinically proved amebic abscess of the liver, admitted on July 31, 1933, to the service of Dr Henry K Mohler and operated upon by Dr Thomas Shallow. This was the only case recorded in this hospital although approximately 3,000 autopsies were performed within this decade. If amebiasis is, or has been, prevalent in Philadelphia either our diagnostic acumen, or our laboratory methods, or our records are at fault.

Various investigators claim that from 50 to 90 per cent of the cases of amebiasis have symptoms not usually dysenteric but mild and attributed to some other factor. It is the latent infections in the carriers and the amebic cysts that are not recognized and become potential dangers both to the host and to the community.

It must be remembered that abscess of the liver may be the first symptom of amebiasis. Ochsner and Bakey⁶ claim that they have found a relatively large number of cases of amebic hepatitis without a history of diarrhea. An explanation may be that slight amebic infection of the bowel, limited to the right half of the colon is less likely to produce diarrhea. On the other hand, Strong⁷ has found a history of dysentery in 60 to 90 per cent of the cases of liver abscess. Three of the four proved cases recently reported by Freund⁸ failed to present any evidence of previous gastrointestinal symptoms. Rogers,⁹ in 1930, reported that in 20 per cent of the cases of amebic abscess of the liver coming to autopsy in Calcutta there had been no history of dysentery. However, he found amebic ulcers, limited to the cecum and ascending colon, in 77 per cent of such cases and ulcer scars in 20 per cent more—a total of 97 per cent which yielded pathological evidence of intestinal amebiasis.

Because of the apparent rarity of amebic abscess of the liver in this climate and because of its occurrence in a patient without previous history of amebic dysentery, the report of the following case, diagnosed following operation, should be of interest.

CASE REPORT

History. J. L., white, 58, Polish, a tanner unemployed for five years, was admitted to the Philadelphia General Hospital on September 16, 1935. Because of the language difficulty and the ignorance of the patient a good history was not obtainable. He claimed that he had been well until September 9, 1935 when he noticed a sudden onset of severe pains in the right upper abdomen, griping in character, coming on every hour or hour and one-half and lasting for 15 minutes. The pains had no relationship to food and were not associated with nausea, vomiting or diarrhea. He had persistent hiccoughing. There were no symptoms referable to the cardiac or respiratory systems. He was chilly, had fever, and felt quite drowsy.

In his past medical history he did not remember having had any childhood diseases or of having had any previous illness, hospitalization or operation. He had never been jaundiced. He had never had dysentery or blood in his stools but contrarily had been constipated. He had not traveled outside of Philadelphia. There was no history of his having come in contact with carriers.

After the operation and after a month of repeated questioning of the family we were able to procure some additional information from the patient's daughter. She stated that for a period of 15 years her father had had pains in his right upper abdomen with heartburn independent of the taking of food. There were attacks of abdominal cramps, without diarrhea, coming on twice a week and lasting 24 hours, associated with chilly sensations. These pains were relieved in one hour by taking a tablespoonful of coal oil with sugar. Upon further investigation it was learned that his son-in-law, who lived in the same house, had been treated at the Jefferson Hospital since September 1933 for a bloody diarrhea. Repeated stool examinations failed to reveal the presence of the ameba. As far as we could ascertain, no other member of the household was affected.

Examination The patient was a slightly emaciated and dehydrated adult male who appeared distressed. The conjunctivae were not icteroid. The nose, mouth and throat were negative. The heart seemed normal. The systolic blood pressure was 115 and the diastolic pressure was 85 mm of Hg. The chest was emphysematous. The bases of the lungs were hyperresonant without any apparent fixation of the diaphragm. The abdomen revealed moderate fullness in the epigastrium over which area there were pains and tenderness which were made worse upon breathing. The upper limit of the liver dullness commenced in the fifth intercostal space anteriorly in the mid-clavicular line and extended 6 centimeters below the costal border. The lower edge of the liver could not be palpated because of the voluntary rigidity of the upper abdomen. The lower abdominal wall was relaxed. The spleen was not palpable, nor enlarged on percussion. There were no signs of fluid in the abdominal cavity. Rectal examination revealed normal sphincter control and no masses. The prostate was slightly enlarged. The examination of the skin and of the nervous systems was negative.

The temperature ranged between 100.4 and 102.1 degrees F. The pulse rate was 94 to 100 per minute and respirations were 30 per minute. The first blood count was Hb 14 gm, rbc 3,840,000, wbc 16,000 per cu mm of which 96 per cent were polymorphonuclear. Of the latter 26 per cent were segmented and 70 per cent were stab forms. The lymphocytes constituted 2 per cent and the monocytes 2 per cent. There were no eosinophiles. The urine showed traces of albumin and was negative for bile. The Wassermann was negative. The urea was 10 mg and the sugar was 90 mg per 100 c.c. of blood. The icterus index was 10.

In the absence of a history of dysentery and because of the sudden onset of the distressing symptoms and signs suggestive of acute suppurative cholecystitis with secondary hepatitis, the patient was operated upon by Dr. Patrick McCarthy on September 18, 1935.

Upon entering the peritoneal cavity he found the gall-bladder and spleen to be normal. The left lobe of the liver was much enlarged and extended down to the umbilicus. The right lobe showed nutmeg-like surface markings and across its lower border extended a deep transverse scar about three-quarters of one inch deep which gave it the appearance of a luetic liver. Further palpation revealed another such scar running vertically and situated at the dome of the right lobe. Towards the middle of the right lobe an area protruded somewhat above the general liver surface which was bluish-gray in appearance. This area was found to be soft and fluctuant. Aspiration of the abscess yielded a thick, whitish pus. A cannula and suction drained off 10 ounces of a thick, creamy, slightly brownish pus. A 24 gauge catheter was introduced in the abscess cavity and sutured in place to the liver. The area about the liver opening was packed with iodoform gauze and the peritoneal cavity was closed.

The pus was immediately examined by Dr Jefferson Clark who found the *Endameba histolytica*. The amebae were of large size with faintly visible nuclei and distinct refractile ectoplasm. They exhibited marked motility and contained vacuoles and occasional red blood cells. The cultures made from the pus revealed *Bacillus coli*.

Dr R. P. Custer's examination of the liver tissue removed at the time of the operation revealed a marked chronic proliferative peri-portal hepatitis.

Two days following the operation the distressing symptoms subsided. The temperature returned to normal where it remained. The drain was removed in seven days after which the incision healed and convalescence was uneventful. The patient was able to resume a full diet.

FIG 2 (1 and 2) *Endameba histolytica* Vegetative forms removed from the abscess cavity of the patient. For comparison (3) *Endameba histolytica* Cyst (4) *Endameba coli* Vegetative form (5) *Endameba coli* Cyst form $\times 2024$

After his return to the medical service, the first week in October, further studies were inaugurated. The bromsulphthalein test showed no retention beyond 30 minutes. The gastric analysis was normal. Ten stool examinations done while in the hospital were negative for ameba and for cysts. Duodenal drainage did not reveal the presence of the ameba. The Craig complement fixation test was not performed.

The proctoscopic examination revealed that the anus showed a fissure at the posterior commissure. There was a nest of internal hemorrhoids. The lower 10 centimeters of the bowel were normal showing no evidence of ulceration.

A roentgen-ray of the chest was normal. The diaphragm was not altered in function or position. Roentgenographic study of the colon revealed that barium passed uninterruptedly from the rectum to the cecum. There was a marked reduplication of both flexures and ptosis of the transverse colon which lay over the first sacral segment. Numerous annular radiolucent shadows were seen throughout which

were caused by intestinal gas. There was marked irregularity about the cecum but no demonstrable irritability. The appearance was suggestive of some inflammatory processes involving the cecum.

The patient was discharged as clinically relieved on November 21, 1935.

FIG 3 Roentgen-ray of the colon. Note the marked irregularity about the outer edge of the cecum and the ascending colon suggesting an inflammatory process.

TREATMENT

Upon the patient's return to the medical ward amebicidal therapy was instituted. It is interesting to note that, because of abdominal cramps over a period of 15 years, he had been accustomed to take a tablespoonful of coal oil by mouth twice a week and had obtained relief. Kerosine has been used for amebiasis.

Every suspected or proved case of amebic abscess of the liver should be given the advantage of a course of emetine therapy before any other procedure is used unless there is an apparent surgical complication. However, Reed¹⁰ believes

that intensive emetine treatment should be avoided before operation because of the possible harmful effect on the myocardium

If the symptoms and signs persist after amebicidal therapy then surgery is indicated. Although there may be multiple amebic abscesses of the liver, the majority are solitary and in the right lobe of the liver, and are sterile. In Ochsner and Bakey's⁵ series of 386 collected cases where smears and cultures were made from the pus of amebic abscesses of the liver, 328, or 83.9 per cent, were found to be sterile. In their own 46 cases, 41, or 89 per cent, were free from bacteria. The consensus of opinion is that closed drainage is the method of choice. It is based on the experience of Rogers² who has shown that the mortality rate of open drainage was as high as 56.8 per cent while in closed drainage the rate decreased to 14 per cent. In Ochsner and Bakey's⁵ 4,035 collected cases, following open drainage there were 1,908 deaths, a mortality rate of 47.2 per cent. In the 459 cases treated by closed drainage and the administration of appropriate doses of emetine they found 32 deaths, or a mortality rate of 6.9 per cent.

When smears of the abscess contents examined at the time of aspiration show the presence of a large number of microorganisms, or when fluid re-accumulates in spite of repeated aspirations, and when there are indications of surgical complications, such as beginning perforation, then open drainage is to be preferred. In all other cases the consensus of opinion is that open drainage is contraindicated.

Immediately after the operation intramuscular injections of emetine hydrochloride should be given in doses of 1 grain daily, not exceeding 10 milligrams per kilogram of body weight. The average adult should not receive more than 10 grains.

Amebicides as acetarsone, carbarsone, tryparsol, chiniofon and vioform are safer and more efficient in the treatment of amebic dysentery. Leake¹¹ believes that they should not be used in amebic hepatitis and liver abscess because they may be toxic to the liver.

SUMMARY

If amebiasis is present in between 5 and 10 per cent of the American population, it is of interest that the records of the Philadelphia General and Jefferson Hospitals contain so few diagnosed cases. Since the Chicago epidemic more cases are being discovered. In Philadelphia amebic liver abscess is still rare. At the Jefferson Hospital during the last decade there was one case among approximately 120,000 admissions and 3,000 autopsies. During the same period at the Philadelphia General Hospital among approximately 232,000 admissions and 24,000 autopsies there were five proved cases. Three, including this case, were discovered clinically and two at autopsy.

It must be remembered that in a high percentage of cases the first symptom of amebiasis may be an abscess of the liver, as occurred in this case. The time elapsing between the infestation and the appearance of the liver abscess may vary from a few months to many years. The symptoms and signs may simulate any surgical liver condition. There may be moderate leukocytosis but no eosinophilia. In the absence of a history of amebic dysentery the primary lesions in the majority of instances can be located in the cecum and ascending colon which

would produce no diarrhea. The roentgen-ray examination by a contrast enema will reveal the local lesions as was found in this case.

In the absence of myocarditis every suspected or proved case should receive emetine therapy before any surgical procedure. Closed drainage is the method of choice. Open drainage without irrigation is indicated when there is beginning perforation or a mixed infection or re-accumulation after repeated aspirations and emetine therapy. It is the consensus of opinion that the arsenicals and oxyquinoline groups of drugs should not be used in the presence of liver damage.

The author wishes to acknowledge due thanks to Dr. Jefferson Clark, Director of Laboratories of the Philadelphia General Hospital, for his extreme cooperation.

EDITORIAL

SEQUELAE OF ASPHYXIA DURING NITROUS OXIDE ANESTHESIA

NITROUS oxide-oxygen anesthesia is generally considered the safest of the general anesthetics. This belief is founded on a number of statistical studies of the anesthetic deaths occurring in very large series of general anesthetics from many countries. It is no doubt correct. Nevertheless most experienced anesthetists stress the need of particular watchfulness in the administration of nitrous oxide and the necessity of experience in its use before prolonged periods of deep surgical anesthesia are attempted.

To many internists who have had occasion to watch patients through nitrous oxide-oxygen anesthetics the reputed safety of this anesthetic must seem remarkable. Figures indicating that it causes death only once in one to five million cases are scarcely credible in the face of the obvious risks entailed in the state of semi-asphyxiation evidenced by these patients. Often this incredulity is heightened by a personal memory of one or more unreported fatalities attributable to gas anesthesia. The recent appearance of a very interesting paper by Courville¹ reporting 13 cases of nervous sequelae after nitrous oxide-oxygen anesthesia will probably result—if medical history repeats itself—in numerous further reports of similar instances and perhaps temporarily in an unreasonable degree of apprehension concerning the use of this anesthetic.

In general in the cases described by Courville nitrous oxide-oxygen anesthesia was followed by prolonged coma or stupor, by delirious states, by convulsions, muscular rigidity, extensor spasms, paralyses, etc. Nine of the 13 cases died after an interval of from 40 hours to 26 days. Four recovered, two completely and two with serious residual neurologic and mental defects. Examination of the brains in the fatal cases was carried out with great thoroughness. The macroscopic changes were minimal but histo-pathological studies showed very extensive alterations chiefly in the cortex and in the lenticular nuclei. The most striking of these lesions were areas of patchy necrosis of the superficial, intermediate or deep cortical layers. Courville considers the cerebral lesions highly characteristic of the effects of cerebral anoxemia as described in experimental animals by Gildea and Cobb,² and others.

While it is generally conceded that nitrous oxide possesses specific narcotic properties, experience has shown that for full surgical anesthesia it is necessary to give gas oxygen mixtures which produce a definite anoxemia. The unconsciousness of deep nitrous oxide-oxygen anesthesia is in part due

¹ COURVILLE, C. B. Asphyxia as a consequence of nitrous oxide anesthesia, *Medicine*, 1936, **15**, 129-247.

² GILDEA, E. F. and COBB, S. The effects of anemia on the cerebral cortex of the cat, *Arch. Neurol. and Psychiat.*, 1930, **24**, 876-903.

to the nitrous oxide and in part to asphyxiation. In the induction of anesthesia many anesthetists use pure nitrous oxide and then change rapidly to a mixture containing approximately 90 to 93 per cent nitrous oxide with 10 to 7 per cent of oxygen for the maintenance of anesthesia. It is of interest to note that Henderson³ in discussing progressive anoxemia classified as the third stage that in which the atmosphere contains between 10 and 6 per cent of oxygen. Concerning the symptoms he states "The subject loses the ability to perform any vigorous muscular movements. Bewilderment and loss of consciousness follow, either with fainting or in a rigid glassy-eyed coma. If revived the subject may have no recollection of this stage. When the oxygen is diminished below 6 per cent, respiration consists of gasps. Convulsive movements may occur. Then the breathing stops but the heart continues to beat for 6 to 8 minutes. Then death."

It is quite apparent therefore that the oxygen percentage in the usual anesthetic mixture is quite low enough to produce definite symptoms of anoxemia and that there is a very narrow margin of safety between the usual percentage and that which would not maintain life.

The mixture inhaled is moreover only one factor in the problem of ensuring an adequate oxygen supply to the cells of the vital centers. Obstruction of the airways, inadequate respiratory movements, pulmonary lesions interfering with absorption, increased circulation time, low hemoglobin content of the blood, factors decreasing the dissociation rate of oxyhemoglobin or the intracellular utilization of oxygen and finally muscular exertion, which greatly increases the body's oxygen needs, may all bring about severe tissue anoxia even in the presence of an adequate oxygen percentage in the gas mixture inhaled. It is obvious, therefore, that the anesthetist has many things to consider in adjusting the mixture to the needs of the individual patient and in combating such impediments to the ultimate tissue use of oxygen as he can alter with the means at his disposal. As to his judgment of the efficiency of the oxygen supply he must be guided by skin and mucous membrane cyanosis, the color of shed blood, and even more importantly by such signs of cerebral asphyxia as forced expiratory movements, clonic and tonic muscular contractions and widely dilated pupils.

It seems strange that as yet we have very few observations on human beings as to the degree of oxygen unsaturation of arterial blood during nitrous oxide-oxygen anesthesia. Those published by Raginsky and Bourne⁴ suggest that there are extraordinary variations in this respect within the range of uncomplicated anesthesia. These authors in a study of 14 cases found that towards the latter part of anesthetics, varying in duration from 10 to 30 minutes, the arterial blood showed oxygen unsaturation varying between 53.3 and 51.1 per cent. Since the mixture administered contained approximately 20 per cent of oxygen, instead of the more usual

³ HENDERSON, Y., and HAGGARD, H. W. Noxious gases, 1927, Chemical Catalogue Co., New York, p. 98.

⁴ RAGINSKY, B. B., and BOURNE, W. Cyanosis in nitrous oxide oxygen anaesthesia in man, Canadian Med. Assoc. J., 1934, xxv, 518-521.

7 to 10 per cent, the extreme degrees of unsaturation encountered are all the more astonishing. There is real need of more extensive investigation of this subject.

If, in a patient under nitrous oxide-oxygen anesthesia, breathing stops temporarily or there is circulatory failure, a period of intense tissue anoxia will be superimposed upon a preceding period of relative asphyxia. It is in such cases especially that cerebral damage may be sustained which will be manifested after resuscitation by the sequelae which Courville has described. In experimental animals with artificially induced cerebral anemia 2 to 15 minutes of anoxemia have been found to cause in most instances irreparable changes in the cerebral cortex and medulla.

In Courville's nine fatal cases of residual coma and convulsions following nitrous oxide-oxygen anesthesia there were six in which during the anesthesia periods of respiratory failure had occurred and in four of these six cardiac failure had also been noted.

In one of these six cases, however, the duration of the anesthesia was brief, "only a few minutes" and the period of cardiorespiratory failure lasted only 4 to 5 minutes, yet this case developed coma, convulsions, extensor rigidity and irregular breathing and died on the fourth day. Moreover, there were three fatal cases in which the period of anesthesia was neither unusually long nor marked by any striking evidences of distress. Such instances suggest a factor of individual susceptibility and this possibility is enhanced by consideration of the many instances of all varieties of severe asphyxia which recover with no apparent residual defects.

Courville's contribution to the toxicology of nitrous oxide-oxygen should arouse interest in a more careful study by modern methods of the effects of this anesthetic upon internal respiration.

REVIEWS

Clinical Heart Disease By SAMUEL A. LEVINE, M.D., F.A.C.P., Assistant Professor of Medicine, Harvard Medical School 445 pages, 97 illustrations W. B. Saunders Co., Philadelphia 1936 Price, \$5.50

This volume has been written primarily for the general practitioner. It stresses bedside and clinical observations. It is especially valuable in that it presents many useful clinical points, derived from the rich experience and accurate observations of the author, not ordinarily found in more pretentious volumes. At times the author is apt to theorize a bit, but it is clearly stated when he is so doing.

There are chapters on the important etiological types of heart disease including a better chapter on functional heart disease than the reviewer has seen in any similar book, chapters on paroxysmal rapid heart action, prognosis, and treatment. Acute cardiovascular emergencies, the clinical significance of the systolic murmur, the patient with heart disease as a surgical or obstetrical risk are discussed in chapters that are excellent and of great practical importance. Chapter XX presents in 113 pages all the practitioner needs to know about electrocardiography.

The style is pleasant and readable, to the point but not too concise. The book is highly recommended.

W. S. L., JR.

The Specificity of Serological Reactions By KARL LANDSTEINER, M.D., The Rockefeller Institute for Medical Research, N. Y. 178 pages Charles C. Thomas, Springfield and Baltimore 1936 Price, \$4.00

Over the course of some years, as the result of the researches of a number of investigators, our conception of the antigen has been considerably modified, and, with this, our ideas about the specificity of the antigen-antibody reaction. A critical review of this work is, therefore, not unneeded. The present book is essentially a translation of the German edition with such alterations and additions as were found necessary to bring it up-to-date. After a short introductory chapter, devoted largely to a clarification of the meaning of specificity, there follows a discussion of the serological specificity of proteins. Next the specificity of cellular antigens is considered and then that of the various antibodies. But the very heart of the work is to be found in the last two chapters, where are presented the investigations on artificial conjugated antigens, so largely carried out by Dr. Landsteiner and his collaborators, and on the chemistry of the specific cell substances—carbohydrates and lipoids. Well organized, clear and concise, with an extensive bibliography, this book presents an excellent review of the subject. Though intended primarily for specialists in the field of immunology, it is not too technical for others who may be interested in this branch of science.

F. W. H.

The Principles and Practice of Medicine Designed for the Use of Practitioners and Students of Medicine. Originally written by the late SIR WILLIAM OSLER, Bt., M.D., F.R.S. Twelfth Edition, Revision by THOMAS MCCRAE, M.D. 1196 pages D. Appleton-Century Co., Inc., New York and London 1935 Price, \$8.50

During the past 10 years, this textbook has not been seen in student hands as often as newer, but possibly less valuable works. This may be due to the infrequency of editions, the present one being only the second since 1925. It is indeed a pleasure

to examine this edition, which has been entirely reset in a type that is distinctly easier to read, as the revisor notes

The preface states, "There are changes and additions in practically every part of the book, perhaps more especially in the discussion of diagnosis and treatment. Certain sections are new or have been materially altered." These changes have been made, however, and the new material added, without sacrificing any of the clearness, simplicity, or completeness of the old text. The original style has been preserved, as well as most of the familiar expressions, while the old and new material is blended smoothly.

It is certainly to the student's advantage to study a text whose original manuscript and subsequent revisions have been in the hands of only two persons. Some recent texts suffer, in contrast, from their multiple authorship. The present volume is striking in its uniformity of style and quality and its conservative modernness.

T N C

An Index of Differential Diagnosis of Main Symptoms. By various writers, Edited by HERBERT FRENCH, CVO, CBE, MA, MD, FRCP. 5th Edition. xii + 1145 pages. Wm Wood and Co, Baltimore. 1936. Price, \$16.00.

This is the most recent edition of a well-known work, first published in 1912 as a companion volume to the publishers' "Index of Treatment." With "An Index of Prognosis, and End Results of Treatment," edited by P. Rendle Short (*Ann Int Med*, 1933, vii, 677-678), it makes up a three volume set, although a different style of binding prevents uniformity of appearance.

The text consists of 925 pages, in which symptoms are listed in alphabetical order. Following each symptom is a discussion of the differential diagnosis of those conditions in which it may be observed, with a fairly complete description of each disease under its most important symptom or physical sign. The index of the book (pages 927 to 1145) is very complete, and must be used if satisfactory results are to be obtained, as the general alphabetical arrangement is incomplete and not cross-indexed.

On the whole, "An Index of Differential Diagnosis" is well written, interesting in style and readable. There are a large number of differential diagnostic tables. The book is fully and beautifully illustrated, having 742 illustrations, of which 196 are colored. Many temperature charts are also included, which, with the illustrations and differential tables, should be very useful for instruction of students.

Unfortunately, as with any work of multiple authorship, there is a tendency toward unevenness of quality. For example, in the long article on jaundice (pages 395 to 416) there is no mention of hemolytic jaundice as such, the different types of hemolytic jaundice being classified under other headings. Thus, the jaundice of malaria is classified with that due to acute fevers and infections, while icterus neonatorum, acholuric jaundice (congenital hemolytic), and paroxysmal hemoglobinuria are placed under "Jaundice Due to Unclassified Causes." The Van den Bergh reaction is poorly described, and the indirect reaction and quantitative estimation of serum bilirubin are not mentioned. Jaundice from cinchophen is not described.

Among other defects are the failure to list lymphogranuloma inguinale as a cause of swelling of inguinal lymph nodes and, in the differential diagnosis of coma, the omission of methyl alcohol or methyl salicylate poisoning. In the section on edema, the effect of depletion of blood plasma protein is not mentioned. In discussing typhus fever, the statement is made that "there is no known serum test for this disease" (p. 681), nor does the Weil-Felix reaction appear in the index.

In spite of these and other faults, the work should prove a very helpful one. Most of the articles are up-to-date and comprehensive. It is almost certainly the most useful of the three "Index" volumes offered by the publisher.

T N C

Human Pathology A Textbook By HOWARD T KARSNER, M D, Professor of Pathology, Western Reserve University Fourth Edition, Revised 1013 pages, 17 X 23.5 cm J B Lippincott Company, Philadelphia 1935 Price, \$10.00

This textbook appeared in its first edition in 1926. Since that time it has been periodically reedited and revised to reflect the continuance of productive effort and accomplishment that the last decade has brought about. The teacher and author, who sets for himself the task of compiling a textbook for students' use, has a multiple problem on his hands. The book must be clear, complete but concise, and must necessarily evaluate, judiciously, the subjects discussed. He further obligates himself, to some degree, to keep the subject matter abreast of the times. Karsner has attempted to fulfill these prerequisites.

The book is divided into two parts, 428 pages being devoted to a consideration of general pathology and 585 pages to pathologic manifestations in the various systems. This arrangement is consistent with the method of teaching pathology in the majority of medical schools. The opening chapter deals with the general phenomena of disease and leads through the more simple processes of pigmentation, degeneration and vascular disturbance to the more complicated subjects of inflammation and neoplasms. Under physical causes of disease the effects on tissue of irradiation are emphasized over previous editions because of the more widespread use of x-ray and radium in the treatment of malignant disease. There are two additions under infectious granuloma that were not present in the earlier editions. These are tularemia and lymphogranuloma inguinale. The chapter on tumors has been almost completely rewritten, without change in the classification. There are also noteworthy changes in the chapters on the hematopoietic system and ductless glands. This has necessitated minor changes in the discussions on tumors in the various systems.

There is some consideration given to the virus diseases as they affect the central nervous system, but no specific mention of lymphocytic choriomeningitis is made. The so-called Rickettsial diseases, typhus, spotted fever, tick fever, are not listed in the index. These are of especial interest in certain localities.

The outline at the beginning of each chapter is especially helpful to the student. The illustrations are well selected and for the most part original. Many are reproduced from drawings. This often exaggerates detail and adds to the clarity of the reproduction. The references are well selected, mostly in English and easily accessible in alphabetical order at the end of each chapter. There are more than 300 new references in this new fourth edition.

The book is primarily a text for students and in this it well fulfills its purpose and further it offers the average practitioner a ready and easily accessible source of information on pathology.

COLLEGE NEWS NOTES

LIFE MEMBERSHIP

Some years ago the Board of Regents of the American College of Physicians, believing a sound financial foundation to be one of the best guarantees of insuring the stability and perpetuity of the College, provided for the building up of an Endowment Fund, "the principal of which shall be held intact and invested in securities approved by the Board of Regents, while the income shall be available for carrying out the purposes of the organization." This Endowment Fund has been built up primarily through Life Membership Fees, the income from which has materially helped in carrying on the work of the College, especially the promotion of scholarships, fellowships and awards, and may help materially in the furnishing of the new College Headquarters.

The Life Membership Fee, ranging from a minimum of \$100.00 to a maximum of \$300.00, plus the original Initiation Fee, depending upon the age of the member at the time Life Membership is taken out, entitles each Fellow or Master to permanent privileges of membership, to the benefits of the Annual Sessions and to the official publications of the College, including the Directory and the *ANNALS OF INTERNAL MEDICINE*. They receive an appropriate Life Membership Certificate, as illustrated in the Directory of the College, and their names are added to the permanent roll of contributors to the College Endowment Fund. Life Members are *active members for life*.

The plan affords the member an opportunity of paying his full dues during his productive years, while his income is greatest, thus avoiding the burden of dues later in life. The plan is one that provides a means for underwriting dues years in advance, but of receiving the premium of active membership throughout one's entire life. A member pays no more for Life Membership than he would pay for ordinary active membership to sixty-five years of age, without active membership thereafter, yet he receives active membership not only until sixty-five, but for the balance of his life. Many members can readily afford Life Membership during their active, productive years, but, with changing conditions or ill health, find annual dues a burden in later life.

The Life Membership plan of the College is bound to be a successful one because it is two-sided: it is good for the member and it is good for the College. It protects the individual's membership for life, it establishes an Endowment Fund for the College, which must be kept intact, the income only to be used for current needs.

Dr. R. L. Leak, Superintendent of the Connecticut State Hospital, Middletown, Conn., has become a Life Member of the College under date of November 25, 1936.

COLLEGE LIBRARY

With the acquisition of an appropriate headquarters for the American College of Physicians with adequate facilities for housing more appropriately the Library of books written by members of the College, there has been an impetus given to the donation of books by the authors. We are gratified to acknowledge receipt of the following gifts by the authors:

Books

Dr. Wyndham B. Blanton (Fellow), Richmond, Va.—autographed books (1) "Medicine in Virginia in the Seventeenth Century", (2) "Medicine in Vir-

- gimia in the Eighteenth Century", (3) "Medicine in Virginia in the Nineteenth Century",
- Dr William B Castle (Fellow) and Dr George R Minot (Fellow), Boston, Mass — 1 autographed book, "Pathological Physiology and Clinical Description of the Anemias",
- Dr Jacob Gutman (Fellow), Brooklyn, N Y — 1 copy, Eighth Supplement to "New Modern Drugs",
- Dr Samuel A Levine (Fellow), Boston, Mass — 1 autographed book, "Clinical Heart Disease",
- Dr Robert L Levy (Fellow), New York, N Y — 1 book, "Diseases of the Coronary Arteries and Cardiac Pain",
- Dr Jonathan C Meakins (Fellow), Montreal, Que — 1 book, "The Practice of Medicine",
- Dr William C Menninger (Fellow), Topeka, Kan — 1 autographed book, "Juvenile Paresis",
- Dr Martin E Rehfuss (Fellow), Philadelphia, Pa — 1 autographed book "The Medical Treatment of Gall Bladder Disease",
- Dr Arthur Havley Sanford (Fellow), Rochester, Minn — 1 book, "Clinical Diagnosis by Laboratory Methods",
- Dr W D Sansum (Fellow) and Dr R A Hare (Fellow) Santa Barbara, Calif — 1 autographed book, "The Normal Diet and Healthful Living",
- Dr LeRoy Sante (Fellow) St Louis, Mo — 2 books (1) "Manual of Roentgenological Technique", (2) "Injuries to the Bones and Joints, Roentgenologically Considered",
- Dr Torald Sollmann (Fellow) Cleveland Ohio — 1 autographed book "A Manual of Pharmacology and Its Applications to Therapeutics and Toxicology",
- Dr J W Torbett (Fellow), Marlin, Tex — a book of poems, "Centennial Songs"

Reprints

- Dr Grafton Tyler Brown (Fellow), Washington, D C — 1 reprint,
- Dr Charles R Castlen (Fellow), Glendale, Calif — 1 reprint,
- Dr Charles Walter Clarke (Fellow), New York, N Y — 1 survey, "Control of Syphilis and Gonorrhea in the Scandinavian Countries and Great Britain",
- Dr A R Foss (Fellow), Missoula, Mont — 2 reprints,
- Dr D Waldo Holt (Fellow), Greensboro, N C — 1 reprint,
- Dr Herbert T Kelly (Fellow), Philadelphia, Pa — 2 reprints,
- Dr George R Minot (Fellow), Boston Mass — 1 reprint,
- Dr Kenneth Phillips (Fellow) Miami, Fla — 2 reprints,
- Dr Ellen C Potter (Fellow), Trenton, N J — 1 reprint,
- Dr William B Rawls (Fellow), New York, N Y — 1 reprint,
- Major James S Simmons (Fellow), (MC), U S A — 2 reprints
- Dr Walter M Simpson (Fellow), Dayton, Ohio — 3 reprints,
- Dr George E Wakerlin (Fellow), Louisville, Ky — 2 reprints,
- Dr W H Watterson (Fellow), La Grange, Ill — 2 reprints,
- Dr Marcos Fernan-Nunez (Associate), Milwaukee, Wis — 1 reprint,
- Dr Hyman I Goldstein (Associate), Camden, N J — 1 reprint,
- Dr Walter E Leonard (Associate), Hollywood, Calif — 2 reprints,
- Dr Charles B Sanders (Associate), Dallas, Tex — 3 reprints
- Dr Francis H Sleeper (Associate), Worcester, Mass — 2 reprints

The Legation of the Dominican Republic, Washington D C, has contributed to the Library a book, "President Trujillo—His Work and the Dominican Republic"

At the Annual Clinic Day conducted at the Memorial Hospital, Pawtucket, R I, on November 4, 1936, the guest speakers were as follows

- D₁ John Eiman (Fellow), Assistant Professor of Pathology, Graduate School of Medicine, University of Pennsylvania, "Observations on Hypo and Hyper Chloremia",
- D₁ George Morris Piersol (Fellow), Professor of Medicine, University of Pennsylvania, "Importance of Restoring and Maintaining Proper Chemical Balance in Chronic Renal Conditions",
- Dr H L Bockus (Fellow), Professor of Gastro-Enterology, Graduate School of Medicine, University of Pennsylvania, "Regional Ileitis and Ileocolitis",
- Dr H B Wilmer (Fellow), Assistant Professor of Medicine, Graduate School of Medicine, University of Pennsylvania "Glucose Tolerance and Metabolism in the Allergic Individual",
- Dr William D Stroud (Fellow), Professor of Cardiology Graduate School of Medicine, University of Pennsylvania, "Result of Five Years' Study at Pennsylvania Hospital of Various Digitalis Preparations and the Present Attitude Towards Digitalis in the Treatment of Cardio-Vascular Disease"

At last year's clinic the guest group was headed by D₁ James H Means (Fellow) of Boston, Mass The chairman at these meetings is Dr John F Kenney (Fellow) of Pawtucket, R I

Dr Thomas Parran, Jr, Surgeon General of the U S Public Health Service, addressed the College of Physicians of Philadelphia November 14 on "Social Diseases from the Public Health Point of View" The lecture was given under the auspices of the James M Anders Fund, established by the late Dr Anders (Master)

Dr Howard M Jamieson (Fellow), formerly of Wilkes-Barre, Pa, has been appointed Chief of the Pathological Department of the Loughborough and District General Hospital, at Loughborough Leicestershire, England

D₁ Porter Paisley Vinson (Fellow), formerly with the Mayo Clinic at Rochester, Minn, has accepted the appointment as Professor of Bronchoscopy Esophagoscopy and Gastroscopy in the Medical College of Virginia His new address is 300 Medical Arts Bldg, Richmond Va

Dr George Herimann (Fellow), Professor of Clinical Medicine in the University of Texas Medical School, conducted a clinic on "Faints and Fits or Syncopal Attacks" and presented a paper on "Some Newer Aspects of the Problems of Heart Failure" as the guest of the Section of Medicine of the Michigan State Medical Society, Detroit, on September 23, 1936

Dr James Alexander Miller (Fellow and Ex-President), Professor of Clinical Medicine, College of Physicians and Surgeons of Columbia University, has been elected President of the New York Academy of Medicine for a term of two years, Dr Arthur F Chace (Fellow) was elected Vice-President for three years

Dr George A Sherman (Fellow), is now Medical Director of the Oakland County Tuberculosis Sanatorium Pontiac, Mich

Dr Salvatore Lojacono (Fellow), formerly Superintendent of the Morgan Heights Sanatorium, Marquette, Mich, has joined the Staff of the Desert Sanatorium of southern Arizona, Tucson, October 1, 1936

Dr Max Pinner (Fellow), has now established his final and official headquarters at the Hermann M Biggs Memorial Hospital, Ithaca, N Y

Dr Charles R Castlen (Fellow) has resumed practice, after a period of illness, at 501 Glendale Professional Bldg, Glendale, Calif Dr Castlen was formerly located in Seattle, Wash

Dr Edward E Cornwall (Fellow) and Dr Frank Bethel Cross (Fellow) are respectively Chairman and Secretary of the new Section on History of Medicine of the Medical Society of the County of Kings (Brooklyn, N Y)

Dr Cross is also President of the recently reorganized Brooklyn Society of Internal Medicine

Dr Anthony Bassler (Fellow), New York, N Y, will be the guest speaker at the New Orleans Graduate Medical Assembly, March 8 to 12, 1937 The subjects he will present are "Hepatic Insufficiencies in Relation to Bodily Disorders" and round table talks on (a) "A Consideration of Diagnostic Criteria of Peptic Ulcer and Its Treatment", (b) "The Dysenteries—Amebic and Bacillary", (c) "Discussion on Biliary Tract Disease"

The Second Congress of the International Society of Gastroenterology will be held in Paris, France, September 13 to 15, 1937 The subjects to be discussed are "The Diagnosis of Gastric Carcinoma" and "The Acute and Chronic Occlusions of the Small Intestine" This Congress will be followed immediately by the International Congress on Hepatic Insufficiencies to be held in Vichy (ninety miles from Paris) on September 16 to 18 The United States National Committee of the International Society of Gastroenterology has been formed by representatives of the various gastroenterological societies in this country Dr Anthony Bassler (Fellow), New York, N Y, Dr Hyman I Goldstein (Associate), Camden, N J, Dr A C Ivy (Fellow) and Dr Lathan A Crandall, Jr, both of Chicago, and Dr Norman W Elton (Reading, Pa) compose the American group who will present the subject "The Relation of Hepatic Insufficiency to General Nutrition and Especially to the Nervous System" Information concerning membership may be obtained from the President, Dr Anthony Bassler, 121 East 71st Street, New York City

The program of the Eleventh Series of Friday Afternoon Lectures at the New York Academy of Medicine discloses a number of the Fellows of the College as contributors

November 6, 1936 "The Early Diagnosis and Treatment of Hypertensive Cardiovascular Disease," by Dr W W Herrick (Fellow), Professor of Clinical Medicine, College of Physicians and Surgeons, Columbia University,
 November 13, 1936 "The Gall Bladder Problem," by Dr Martin E Rehfuess (Fellow), Clinical Professor of Medicine, Jefferson Medical College,
 January 15, 1937 "Recent Advances in the Treatment of Chronic Arthritis," by Dr R Garfield Snyder (Fellow), Chief of the Arthritis Clinic, Hospital for the Ruptured and Crippled, New York City,

January 22, 1937 "Recent Advances in the Endocrine Field," by Dr David P Bair (Fellow), Professor of Medicine, Washington University,
February 26, 1937 "Modern Concepts of Anemia from the Clinical Standpoint," by Dr Edward B Krumblhaar (Fellow), Professor of Pathology, University of Pennsylvania School of Medicine,
April 2, 1937 "The Diagnosis and Management of the Commoner Clinical Allergies," by Dr Robert A Cooke (Fellow), Assistant Professor of Clinical Medicine, Cornell Medical College,
April 9, 1937 "A Study of Four Hundred Cases of Pulmonary Tuberculosis," by Dr George Foster Herben (Fellow), Physician in Chief, Loomis Sanatorium

Dr Guy W Carlson (Fellow), Appleton, Wis, is President of the Outagamie County (Wisconsin) Medical Society and Secretary of the Sixth Councilor District of the Wisconsin State Medical Society

Dr John H Peck (Fellow), Des Moines, Iowa, has removed to Oakdale, Iowa, where he has accepted the appointment as Superintendent of the Iowa State Sanatorium, November 1, 1936, to fill the unexpired term of Dr J A Edwards, who was killed in an automobile accident during October

Dr J C Kamp (Fellow), Casper, Wyo, has just completed an extended visit to the clinics and hospitals of London and Vienna

Dr Alexsei Leonidoff (Associate) addressed the Dutchess Putnam Dental Society October 29 on 'Diseases of the Heart and Lungs,' pointing out their relations to dentistry

Dr Alfred R Masten (Associate) has been appointed Director of the Division of Tuberculosis Control, Colorado State Board of Health, with offices at 424 State Office Bldg, Denver, Colo

Dr James B Collip (Fellow), Professor of Biochemistry, McGill University Faculty of Medicine, Montreal, Que, received the honorary degree of doctor of science during the Centenary of Harvard University in September

Dr William Thallmer (Fellow) is in charge of the Manhattan Convalescent Serum Laboratory, which has been established in the research laboratory of the department of health for preparation and distribution of immune serums for measles, scarlet fever and other communicable diseases

Dr J Burns Amberson, Jr (Fellow) and Dr Edgar Mayer (Fellow), New York City, have been appointed consultants on dust diseases by the State Industrial Commissioner

Dr Martin L Stevens (Fellow), Asheville, N C, has been appointed a member of the Board of Trustees of the State Tuberculosis Sanatoria

Dr Paul P McCain (Fellow), Superintendent of the State Sanatorium, Sanatorium, N C, was the recipient of the honorary degree of doctor of laws at the annual commencement of the University of North Carolina

Dr Henry A Christian (Fellow) delivered the third Frank Billings Lecture of the Thomas Lewis Gilmer Foundation of the Institute of Medicine of Chicago at a joint meeting with the Chicago Society of Internal Medicine, October 26, on "Edema, Diuretics, Diuresis"

Under the presidency of Dr Frank H Krusen (Associate), Rochester, Minn, The Academy of Physical Medicine held its annual meeting in Boston, October 20 to 22

Dr Jonathan C Meakins (Fellow), Montreal, Que, assisted in the presentation of a symposium on integration of the medical curriculum during the forty-seventh annual meeting of the Association of American Medical Colleges, Atlanta, Ga, October 26 to 27

Dr Chester W Waggoner (Fellow), Toledo, has been appointed a member of the Ohio State Medical Board

Dr Carl S Mundy (Fellow) and Dr Paul M Holmes (Fellow) have been appointed members of the Advisory Health Board, recently created for Toledo. The Board will act in an advisory capacity on all municipal health matters and will confer with the city manager, the health commissioner and the welfare director on current health problems

Under the Presidency of Dr Charles M Griffith (Fellow), Medical Director of the Veterans Administration, Washington, D C, the forty-fourth annual meeting of the Association of Military Surgeons of the United States was held at Detroit October 29 to 31. Dr Perceval S Rossiter (Fellow), Surgeon General of the U S Navy, was installed as President for the coming year. Among Fellows contributing to the program were

Dr Philip B Matz, Washington, D C, "Diabetes Mellitus among Veterans of the World War",

Dr Frederick G Buesser, Detroit, "Treatment of Peptic Ulcer",

Dr William W Hall, (MC), U S Navy, "Active Immunization against Tetanus with Tetanus Toxoid"

Dr John C Ruddock (Fellow), Los Angeles, President of the California Heart Association, gave an illustrated lecture before the seventh annual postgraduate symposium on heart disease of the San Francisco County Medical Society, November 18 to 19

Dr Ernest E Irons (Fellow), Chicago, gave a clinic on pneumonia and Dr Fred M Smith (Fellow), Iowa City, directed a symposium on peptic ulcer in connection with the annual clinic of the University of Iowa College of Medicine, held at Iowa City, November 12 to 14

Dr Edwin W Gehring (Fellow) has resigned as Editor-in-Chief of the *Maine Medical Journal*. The Journal will be continued under the direction of its Editorial Board

The University of North Carolina in connection with its extension division and its School of Medicine is sponsoring a graduate course of lectures in Goldsboro for physicians in the eastern section of the State. Dr Thomas Fitz-Hugh (Fellow), Philadelphia, and Dr Paul D White (Fellow), Boston, were those selected to give the lectures on "Common Forms of Anemia" and "Coronary Diseases," respectively

Dr J Morrison Hutcheson (Fellow), was installed as President of the Medical Society of Virginia during October

Dr David P Barr (Fellow), St Louis, will deliver the Nathan Lewis Hatfield Lecture before the College of Physicians of Philadelphia, January 6, on "Parathyroids and Their Role in Health and Disease". Dr Barr will deliver an address before the New York Academy of Medicine January 22 on "Recent Advances in the Endocrine Field". Dr Barr delivered a lecture on endocrinology at the Medical Institute of the University of Toledo, November 6, on the occasion of its third annual "Postgraduate Day"

Dr Ralph A Kinsella (Fellow), St Louis, addressed the Southwestern Medical Association at its twenty-third annual meeting at El Paso, November 19 to 21, on "Career of the Heart, Differential Diagnosis of Rheumatic Fever"

Dr Arthur C Christie (Fellow), Washington, D C, delivered the Silvanus Thompson Lecture before the British Institute of Radiology at Westminster, December 2

Dr Reginald Fitz (Fellow), Wade Professor of Medicine, Boston University School of Medicine, and Director of the Evans Memorial Hospital, has been appointed Lecturer on the History of Medicine, Harvard University Medical School, for three years. Dr Fitz is university marshal at Harvard and was formerly Associate Professor of Medicine in the Harvard Medical School before accepting the Wade Professorship at Boston University

Dr Horton R Casparis (Fellow), Professor of Pediatrics, Vanderbilt University School of Medicine, Nashville, was the guest speaker at the annual dinner of the Minnesota Public Health Association, Minneapolis, November 13

Dr Allen K Krause (Fellow), Baltimore, addressed the Brooklyn Thoracic Society, October 16, on "Modern Management of Clinical Tuberculosis"

Dr Paul P McCain (Fellow), Medical Director and Superintendent of the North Carolina Sanatorium for the Treatment of Tuberculosis has been appointed manager of a new state sanatorium now under construction at Black Mountain, near Asheville. A unit of the new hospital will be finished by April, 1937. Dr McCain will have charge of both institutions, with assistant managers at each

The Philadelphia County Medical Society adopted a new plan for meetings of its branch societies by arranging a symposium on the diagnosis of syphilis, the symposium being presented in turn before each branch. The speakers were

Dr Jefferson H. Clark (Fellow), laboratory aspects,
Dr Sigmund S. Greenbaum (Fellow), lesions of the skin and mucous membranes,
Dr William Egbert Robertson (Fellow), cardiovascular syphilis,
Dr Michael A. Burns (Fellow), syphilis of the nervous system

Dr James E. Paullin (Fellow), Atlanta, was elected President of the American Clinical and Climatological Association at its annual meeting in Richmond, Va., October 26 to 28.

On the program appeared Dr. Howard F. Root (Fellow), Boston, "Insulin Protamine in Treatment of Diabetes", Dr. Frederic M. Hanes (Fellow), Durham, N. C., "Metabolic Studies in Sprue", Dr. Edgar Mayer (Fellow), New York City, "The Dietary Treatment of Tuberculosis—More Recent Aspects", Dr. Lewis J. Moorman (Fellow), Oklahoma City, "Calcification of the Spleen", Dr. Roy R. Snowden (Fellow), Pittsburgh, "Treatment of the Thyroid Crisis"

Dr. Edward J. Murray (Fellow), Lexington, Ky., has been chosen President of the Southern Tuberculosis Conference

Dr. Roland N. Klemmer (Fellow), Lancaster, Pa., was recently elected as Chief of the Medical Department of the Lancaster General Hospital

DR H F STOLL

OBITUARIES

DR HENRY FARNUM STOLL

Henry Farnum Stoll, M D (Fellow and College Governor for Connecticut), Hartford, Connecticut, died September 28, 1936

Dr Stoll was born in Port Jervis, New York, May 25, 1878, the son of Albert and Elizabeth Farnum Stoll. He received his preliminary education in the public schools of Port Jervis, attended Cornell for two years and then took his medical training at Columbia University, College of Physicians and Surgeons, from which he graduated in 1902

Following his graduation, Dr Stoll served an internship at the Hartford Hospital and then began the practice of medicine in Hartford, Connecticut. His professional career was devoted to internal medicine, to the literature of which he contributed fifty-nine articles. His contributions on the subject of tuberculosis are outstanding, numbering twenty-five

In 1905 Dr Stoll became Assistant Physician to the Hartford Hospital, Assistant Visiting Physician in 1910 and Visiting Physician from 1923 until his death. He also held numerous hospital appointments throughout Connecticut as Consulting Physician

During the World War Dr Stoll served in the Medical Corps of the Army as Captain and Major, being assigned as Instructor in the Diagnosis of Tuberculosis, Army Medical School, Washington, D C

Dr Stoll became a Fellow of the American College of Physicians on April 8, 1929 and Governor for Connecticut in 1930. The College meant a great deal to Dr Stoll and its welfare interested him deeply. He was a member of numerous other medical societies, local, state and national, and a past president of the Hartford County Medical Society

On September 19, 1911, Dr Stoll married Miss Eleanor Roberts who, with his daughter, Miss Hortense Stoll, survives him

Dr Stoll was an energetic, arduous worker and student. His devotion to Medicine, his eagerness in the search for better methods of diagnosis and treatment, and his wise counsel long made him an outstanding medical consultant in Connecticut. Possessed too of a delightful sense of humor he was a most genial friend and companion

With the passing of Dr Stoll, another great physician has been taken from us. Of him one of his own patients has well said, "Though his presence will be keenly missed, the memory of his indomitable spirit will endure through the years and be a source of strength to those who were fortunate enough to be numbered among his friends"

OTTO G WIEDMAN, M D , F A C P

DR ROBERT SPEAR

Dr Robert Spear (Fellow), East Chicago, Ind, died August 23, 1936, aged 68 years. He was a native of Cobourg, Ont. He graduated from the Faculty of Medicine of Trinity University, Toronto, Ont, in 1897.

He served with the U S Army in the World War, was a former member of the East Chicago School Board, and had been a member of the Staff of St Catherine's Hospital in East Chicago since the opening of the institution in 1929. He had practiced in this vicinity since 1897.

Dr Spear was a member of the Lake County Medical Society, the Indiana State Medical Association, the American Medical Association, and had been a Fellow of the American College of Physicians since 1925.

DR GORDON LEE HASTINGS

Dr Gordon Lee Hastings (Fellow), Little Rock, Ark, died September 14, 1936, at the age of 39. For the last three years he had served as Assistant State Health Officer and Director of Rural Sanitation of the Arkansas State Board of Health. He was a native of Virginia and was a graduate of Randolph Macon. His professional degree was conferred by the Medical College of Virginia. After serving an internship at the Stuart Circle Hospital in Richmond, he took postgraduate work at the Rockefeller Training Station at Indianola, Mississippi. In 1929, he came to Arkansas where he made an enviable record in public health work. He obtained a M P H degree in 1935 from the Harvard School of Public Health.

Shortly before his untimely death, Dr Hastings had been elected to the Assistant Professorship in the Department of Public Health Instruction of the University of Michigan. He was at his parental home visiting prior to taking up his new duties when he was suddenly stricken with an acute cardiac failure. He was married and had one son.

Dr Hastings was elected a Fellow of the American College of Physicians in 1934. He was also a member of the Pulaski County Medical Society, the Arkansas State Medical Association, the Southern and the American Medical Associations.

Not of the aggressive type but on the contrary, modest and unassuming, Dr Hastings nevertheless was an outstanding physician in his chosen field. His loss will be mourned not only by his family but by his former confreres and a host of friends.

OLIVER C MELSON, M D, F A C P,
Governor for Arkansas

NUMBER 7

FURTHER STUDIES ON INTOXICATION WITH VITAMIN D ^{*}†

By I E STECK, M D, H DEUTSCH, A B, C I REED, Ph D, and H C
STRUCK, Ph D, *Chicago, Illinois*

WITH the extensive application of massive doses of vitamin D as a therapeutic agent in various clinical conditions ^{1, 2, 3, 4 5, 6, 7} numerous criticisms have arisen which may be summarized as follows

- 1 Hypervitaminosis D may produce symptoms of hyperparathyroidism
- 2 The therapeutic use of vitamin D is rational only in conditions of known deficiency
- 3 Animals experimentally treated with vitamin D concentrates have shown extensive calcium deposits in various tissues, and other pathological changes have been found There is, thus, danger of permanent injury to human subjects

It is not the purpose of this paper to discuss the therapeutic value of concentrated vitamin D in any clinical condition Only by more extensive clinical investigation can its therapeutic value be established finally

That vitamin D in massive doses may be toxic to any individual, animal or human, has been recognized in all stages of this series of investigations which was begun early in 1929, and its administration to human subjects has been governed accordingly It is the purpose of this paper to present evidence bearing on these questions The first of these questions has been discussed very thoroughly by Shelling,⁸ who concluded that the preponderance of evidence is against the view that the activity of vitamin D is dependent upon the functional integrity of the parathyroids and in favor of the existence of an antagonism between the two The second criticism is purely speculative If this idea held true very few therapeutic procedures now in use could be justified

* Received for publication September 26, 1936

From the Departments of Medicine and of Physiology, College of Medicine, University of Illinois, Chicago

† This investigation at various stages has been supported in part by grants from Mead Johnson and Company, the Graduate School Research Fund, University of Illinois, the American Academy of Arts and Sciences, the Wisconsin Alumni Research Foundation, the Committee on Therapeutics of the American Medical Association, and the Phi Rho Sigma Medical Fraternity

In considering the nature of the action of massive doses of vitamin D it is assumed that the action is very different from the physiological effects of small doses. It is so different, in fact, that the concentrated material may be considered tentatively as a different substance. At the same time there is some legitimate doubt as to the justification for this attitude.

Early experience with impure preparations of vitamin D, particularly abroad, has led to a great deal of misunderstanding and fear of overdosage on the part of those who have had little acquaintance with the fundamental mechanisms involved. This point has been adequately discussed by Bills.⁹ Suffice it to say that most of this earlier work must be disregarded when considering the effects produced by the highly purified preparations now available.

EXPERIMENTS ON TOXICITY OF VITAMIN D FOR DOGS

The effects of massive doses of vitamin D must be judged on the basis of the dose per unit body weight and not on the absolute size of the dose. When considered in this light the order of increasing susceptibility appears to run as follows: rat, dog, human, rabbit, with little difference between the dog and human, while the rat is very much more resistant, and the rabbit much less so.

In the experiments on dogs, vitamin D was administered in the form of a solution of activated ergosterol in corn oil* (1,000,000 units per gm) or of calciferol† dissolved in corn oil. Most of the administration was done orally. A few animals received intravenous injections in which form the material is slightly more effective. The results of experiments on 64 adult healthy dogs are shown in table 1. The daily dose ranged from 15,000 to 500,000 units per kilogram of body weight as shown in the first column. An effort was made to adjust the dose to decreasing body weight so that the ratio between the dose and the weight of metabolising tissue remained fairly constant.

The figures in the second column represent the actual number of days of administration of the vitamin D and, therefore, the number of days the animals *survived the treatment*. Usually those that did not die were killed on the day following the last dose, others within two to three days. With amounts greater than 50,000 units daily the average survival period was 12 days, with amounts between 20,000 and 50,000, 39 days, and with 20,000 units or less, 68 days.

At death, tissues were taken for chemical analysis and for microscopic examination. In an earlier report¹⁰ on analyses of 13 different tissues in a series of dogs, it was shown that the kidney is the most vulnerable of any tissue to the calcifying action of vitamin D. In order to conserve space, only the figures for the calcium content of the kidney are included. In all other tissues the findings were very inconstant. Analyses of tissues of normal dogs have shown a calcium content in the kidneys ranging from 29 to 301 mg per 100 gm of dried tissue with a mean of 85 mg. The calcium content in the kidneys of 33 of the 64 dogs is shown in the third column of table 1.

With a daily dose above 50,000 units per kg the average content of calcium in the kidney was 564 mg per 100 gm of dried tissue, between 20,000 and 50,000, 921 mg, and with 20,000 units or less, 183 mg. The lower average in the first group may possibly be related to the shorter period of survival. The average in the third group is obviously lower because the dose was not great enough to cause as much deposition.

In the fourth column the figures represent the maximum concentration of

* Supplied mainly by Mead Johnson and Company, also by Abbott Laboratories, Parke Davis and Company, and Winthrop Chemical Company.

† Supplied by Mead Johnson and Company, Winthrop Chemical Company, and Glaxo Laboratories.

plasma calcium found at any time. The level was not constant in any group. Very high levels were seldom constantly maintained. In figure 1 is shown the distribution of the figures observed in dogs in relation to the daily dose of vitamin D. It is obvious that there is little correlation between the two factors. With daily doses greater than 20,000 units per kg every animal at some time showed very high concentrations, but the level fluctuated greatly in each animal. With lower doses the figures are within the normal range for heparinized plasma.

FIG 1 The blood calcium in 43 normal dogs under treatment with vitamin D. In each column are shown the total number of determinations made on all in each dosage group. Successive determinations on the same dog appear on the same ordinate.

For purposes of simplicity of recording and comparing the microscopic findings, a scale of 1 to 5 arbitrary units was used, although this method is open to some objection. The only striking microscopic findings were degeneration of individual cells and the presence of deeply stained areas of calcium deposition. In recording the degree of cell injury, a unit of 1 indicates the presence of only occasional degenerated cells, two or three in a single field. A unit of 5 indicates a stage in which considerable masses of contiguous cells had undergone degeneration. However, this stage always occurred in conjunction with a comparable stage of calcium deposition. It will be seen that the relationship between the degrees of cell destruction, calcium deposition and calcium content of the tissue varies considerably, but that in general those tissues having the higher calcium content by analysis showed the more extensive injury. These injuries appeared first and were most numerous in the collecting tubules but later were extended quite generally throughout the organ. In only one animal were calculi found in the tubules (No 21, table 1).

It appears that cellular injury occurs first and that calcium deposition then takes place at the sites of these injuries. In four animals (Nos 7, 18, 27, 31) showing extensive damage to the kidney, there was no evidence of

cellular injury nor of excessive calcium deposition in any other tissue examined

From evidence obtained on 12 other animals not included in the table, it appears that considerable loss of weight may occur before there is any evidence of injury to cells, but this was not invariably the case

Our observations do not confirm those of Appelrot¹¹ to the effect that hypervitaminosis D produces medial thickening in arteries. In only four of the 64 dogs examined, i.e., numbers 18, 21, 27 and 29, was this observed. In each case there was some medial thickening in the aorta and occasionally in smaller arteries

Loss of weight was marked in 36 out of the 43 dogs receiving more than 20,000 units per kg per day. One retained constant weight, one gained 17 per cent. As previously suggested,¹² the early weight loss appears to be due mainly to impoverishment of fat depots. When dog No 28 was examined at autopsy it was almost impossible to find any macroscopic fat deposits. This dog lost 48 per cent of the original weight, yet showed only mild objective symptoms of toxicity and was lively and active at the termination of the experiment. There was practically no microscopic evidence of cell injury. The plasma calcium was maintained at a higher average level over the period of the experiment than in any other animal in our experience.

On the other hand, dog No 21 lost only 15 per cent of the initial weight, although the kidney content of calcium was higher than in any other animal. These two animals serve to show clearly that weight loss is not an inevitable accompaniment of fatal intoxication in dogs.

One of the characteristic features of fatal hypervitaminosis D is the premortal coma. This condition is usually, though not always, preceded by partial paralysis, slow, shallow respiration, fine, thready, rapid pulse, salivation, and often by psychic changes of such a nature that a previously tame, friendly dog may become unmanageable and even vicious. Very often the symptoms resemble those following an injection of oil of wormwood. This condition may persist for several days but usually appears from two to three hours before death. It is probable that all of the dogs labelled "found dead" passed through this stage during the night, but the actual train of symptoms could not be observed. None of the animals that were killed were in this stage.

The objective symptoms of toxicity were much the same as those previously described for the human,⁴ such as weakness and lassitude, anorexia, polydipsia, polyuria, psychic disturbances, diarrhea. Bloody feces were passed by 11 of the 64 dogs. In addition, petechial hemorrhages were found in the mucosa of the stomach and intestines at autopsy.

With eight exceptions all of the 43 dogs receiving more than 20,000 units per kg per day died spontaneously. Nine of these died from distemper. Of the nine, three were in such a condition that early death in coma was predictable. Of the eight exceptions, one was allowed to recover. Of

the seven that were killed, two would probably have died. The other five would probably have recovered with cessation of the treatment.

Among the 20 dogs receiving 20,000 units or less per kg there were no evidences of cell injury, insignificant weight loss, very little evidence of toxic symptoms, and with the exception of two dogs that died from distemper and one that was allowed to recover all were in good condition when killed.

Thus, it may be concluded that vitamin D up to 20,000 units per kg per day for periods ranging up to 153 days is not seriously injurious to normal dogs. In greater amounts there is a wide range of susceptibility entirely unpredictable from any data at present available.

That the toxic effects may be characterized as true hypervitaminosis D is proved by the fact that in four instances (numbers 7, 17, 29, 34) the vitamin preparation administered was crystalline calciferol (40,000,000 units per gm) in solution in corn oil. This preparation contained *no* toxic by-products and yet the results were quite comparable with those from the same dose of activated ergosterol which may contain some inert material but practically no toxisterol.

In another series of experiments the dogs were brought to a stage of extreme toxicity with vitamin D and the administration was then discontinued. The state of toxicity was manifested by loss of weight, anorexia, listlessness and paralysis, and, in six animals, prostration. After varying intervals, when there was objective evidence of complete recovery, the animals were killed and subjected to the same examination as in the other series. The results are shown in table 2. In the first column are shown the periods

TABLE II

No	Days	Recovery Days	Units/K/Day	Kidney Ca	Max Blood Ca	Microscopy		Wt Loss Per Cent

10	15	8	105,000	218	18.72	—	—	30	Still 15 per cent under weight Fair condition 10 per cent under weight

of administration of the vitamin, in the second the daily dose per kg, and in the third the recovery interval allowed. Actually in the dogs No 4, 6, 7 and 8 complete recovery of weight was accomplished in 53, 86, 73 and 60 days respectively. Animals No 9 and 10 were killed before weight

recovery was complete because both were definitely overweight when the experiments were begun

Eight additional dogs were originally included in this series but all of these were in the terminal stages of toxicity described above when the treatment was discontinued, and all died within two to seven days. Six of these were already prostrate when administration was discontinued.

In all but one (dog No. 4) the kidney content of calcium was within the normal range, although all showed figures in the higher limits of the normal range except Nos. 2 and 7. The average weight loss approximated that in comparable dosage ranges in the first series.

The maximum concentrations of plasma calcium observed were all high. Microscopic examination of the tissues showed no definite evidence of calcium deposition and no cellular injury. In Nos. 2 and 5 there was some distortion of the collecting tubules in the kidney by fibrosis. No vascular lesions were found.

From these experiments it appears that dogs may recover from extreme stages of toxicity and that whatever tissue injury occurs may be repairable. In extremes the result may be fatal before repair can be effected.

In the experiments on animals reported by others, so far as the potency of the dose can be calculated, toxicity has occurred only with doses above 20,000 units per kg. per day. Since the relation of dosage to weight has not been stressed before, many other workers have failed to record data which would make it possible to calculate the dose in terms of units per kilogram.

In both of our series it is apparent that the total amount of vitamin administered is not the most important determinant of the degree of toxicity since large doses have been tolerated well over long periods while smaller doses have produced drastic effects in a few days. Nor is the magnitude of the daily dose the sole factor. In general both dogs and human subjects appeared to be less sensitive during winter months.

TABLE III

Dog No	1	2
Units/kg./day	60,000	30,000
Initial plasma Ca	11.60	10.89
5th day	12.03	14.62
7th day	12.00	13.90
14th day	14.00	12.44
15th day	11.30	11.79
16th day	12.57	11.12
21st day	12.10	12.15
22nd day	11.34	—
23rd day	12.00	13.25
24th day	dead	—
26th day		12.24
30th day		9.70
31st day		13.00
32nd day		11.93
33rd day		dead

It has been emphasized many times that the diet is a very important factor in conditioning toxicity. All of these animals were kept on the stock kennel diet throughout and no variations were introduced at any time.

It is also apparent that the concentration of plasma calcium is not closely correlated with toxicity. Many investigators have been inclined to use the terms "hypercalcemia" and "toxicity" interchangeably. Many experiments have been done which clearly disprove a causal relation between these conditions but the two experiments reported in table 3 will serve to illustrate the point. Both of the animals showed some hypercalcemia, but it was by no means pronounced. Number 1 received twice the dose of number 2, but except for the earlier death there was no striking difference. When one contrasts these figures with the high figures for some of the animals that survived as in tables 1 and 2, it is a fair assumption that hypercalcemia per se is not the cause of toxicity.

OBSERVATIONS ON HUMAN SUBJECTS

The enormous absolute doses of vitamin D that have been administered to human subjects have naturally aroused some question. If, however, one bears in mind that human and canine susceptibility seem closely approximated, and if one gives due consideration to the weight/dosage relationship, it appears that few of the human subjects have ever received amounts comparable to the highest doses tolerated by the dogs of this series.

TABLE IV

	Male			Female		
	Total No	No Toxic	Per Cent	Total No	No Toxic	Per Cent
Postoperative tetany	2	0	0	15	4	26.4
Hay fever and asthma	178	13	7.3	322	24	7.4
Arthritis	43	5	11.6	107	11	9.4
Miscellaneous	12	1	8.3	23	3	13
Normal subjects	63	1	1.5	8	1	12.5
	298	20	6.7	475	43	9
Total subjects					773	
Number toxic					63	
Per cent toxic					8	

Table 4 shows the status of 773 human subjects who have received amounts of vitamin D above 100,000 units daily. The doses routinely given ranged upward from 200,000 units total daily dose for periods ranging from seven days to five years. With such a dose a 50 kilo subject would receive only 4,000 units per kg per day. With 300,000 units a 60 kg subject would receive 5,000 units per kg per day. This table, of course, does not take into account the varying dosages, so that one cannot draw conclusions as to comparative susceptibility in the various groups of subjects. However, it ap-

pears, from other statistics too voluminous to include here, that the order of decreasing susceptibility among the different groups of patients is arthritis, normal subjects, hay fever alone, hay fever with asthma, tetany

TABLE V

Units/kg /day	No	No Toxic at any Stage	Per Cent Toxic
1500-3000	5	5	100
3000-5000	555	25	4.5
6000-7000	123	18	14.6
8000-15,000	70	11	15.7
15,000-25,000	16	3	18.8
25,000-35,000	4	1	25
	773	63	8+

In table 5 the incidence of toxicity at each range of dosage is shown. This analysis does not take into account the duration of administration since, as was indicated by the experiments on dogs, the total amount does not seem to be the most important factor. Nor does it take into account the effect of simultaneous administration of yeast as a protective measure which was done with many human subjects. This procedure has already been discussed rather fully.^{4, 5} The first five subjects may be disregarded since they became nauseated from corn oil as readily as from viosterol, so that they do not represent true hypervitaminosis D, but rather some kind of sensitivity not related to the vitamin. It is probable that some of those subjects included in the toxic groups at higher dosage were of this type. The shortest period of administration that produced intoxication in the group on 3,000 to 5,000 units per kg per day, was 87 days. Since the condition in this instance developed very suddenly and without any weight loss, it is possible that some unrecognized disturbance rendered the subject temporarily more susceptible. On discontinuance of administration of vitamin D prompt recovery occurred, and four days later the treatment was resumed and continued four months without further disturbance.

In the group on 6,000 to 7,000 units per kg per day the shortest period for development of toxicity was 60 days. In this instance there was a loss of four pounds in two days. The condition was abated sufficiently to resume only after eight days without treatment. A second mild intoxication occurred three months later.

In the last two groups the high doses were not continued beyond 10 days except in one case, regardless of whether intoxication occurred. In this case one of the authors, a normal subject, took 35,000 units per kg per day (3,000,000 units total daily) for 15 days without any evidence of disturbance of any kind.

Vrtaak and Lang⁷ have recently reported 100 per cent incidence of toxicity in a series of 22 human subjects to whom massive doses of vitamin D

were administered. The discrepancy between this high incidence and the relatively low incidence in our series is difficult to explain at present.

The symptoms of hypervitaminosis D in human subjects were described fully in an earlier paper.⁴ It remains now to correlate these findings with the experimental results on animals. Tentatively we suggest that the course of events is as follows. First, cellular degeneration occurs, more commonly in the kidney. Concurrently there may be loss of weight and other objective symptoms. If weight loss occurs before other symptoms it is probably due solely or mainly to increased fat catabolism. Second, deposition of calcium occurs at the sites of cell injury, apparently this does not occur except as a secondary result of such injury. Third, up to advanced stages of toxicity these processes may be repairable in dogs if the vitamin D administration is discontinued.

From the results of previously reported work^{10, 12} it appears that the calcium removed from the tissues during recovery is excreted in the urine. At least, repair is not complete until the urine calcium excretion becomes normal.

The increased excretion of calcium that usually takes place^{12, 13} under massive administration of vitamin D in both human subjects and dogs is not, however, due solely to removal of the microscopic deposits in the soft tissues, because the increase in the urine begins before there is any microscopic or chemical evidence of excessive deposition in soft tissues. The source of this initial increase in the urine has not yet been determined, but from Shelling's discussion it probably comes from the trabeculae of the bones. Generally the average level of blood calcium is decreased after the excretion is increased.

We have made no examination of blood pressure in dogs, but a large number of the human subjects were examined at frequent intervals over long periods. Since there have been no significant changes the data are omitted. In most instances there seems to be some tendency to a slight decrease in the general level. This, of course, does not eliminate the possibility of medial proliferation in the arterioles.

Our human subjects ranged in age from 17 to 76 years. Older subjects were generally less readily intoxicated but recovered less readily when intoxication did occur, and seemed to be somewhat more sensitive thereafter.

There are on record only two instances of death in human subjects, certainly due to hypervitaminosis D, since the more highly purified preparations became available. One of these, recently reported by Thatcher,¹⁴ was probably a case of idiosyncrasy to vitamin D. It is difficult to determine from the report the unit dosage. However, it is clear that the administration was continued after intoxication was markedly developed.

We wish to stress that administration of vitamin D should be discontinued at once when the symptoms of intoxication appear. Neither animal nor human subjects in our experience have ever recovered from the toxic condition while administration continued.

The other case has not yet been reported in detail in the literature, but the reports of the coroner and the attending physician¹⁶ reveal the following facts. A physician, aged 74, weight 290 pounds, undertook self medication with a concentrated solution of activated ergosterol. Owing to an *error* in calculation of the dosage he received 2,300,000 units daily for 18 days or approximately 18,000 units per kg per day, a dose 10 times that intended. Since he was very obese the dose per kilogram of actively metabolizing tissue was much greater. The symptoms described were quite typical of hypervitaminosis D, with hypercalcemia, so that there is no doubt that in this case the treatment was the immediate cause of death. However, the presence of generalized arteriosclerosis suggests that this was a fundamental handicap to his recovery after discontinuing the treatment.

The administration of similar or larger amounts in our series without serious disturbance should not be interpreted to mean that such treatment can be undertaken without caution. In fact, our experience indicates clearly that administration of massive doses of vitamin D should not be undertaken for any cause except under the careful supervision of a physician who can and will carefully check the patient's condition at frequent intervals and who will see to it that the treatment is discontinued promptly on the appearance of the first signs suggestive of toxicity.

It is probable that any suggestion of kidney dysfunction should constitute an absolute contraindication. Until further information is available arteriosclerosis also should probably be considered a contraindication. Consequently, this form of treatment should be administered to older subjects only with extreme caution.

Nevertheless, if these precautions are observed, massive doses of vitamin D may be utilized therapeutically as safely as many other agents administered daily. That its misuse has resulted in death should not prejudice its controlled use under circumstances of possible value.

In view of the extensive experience in administration of vitamin D to human subjects with a relatively low incidence of toxicity, and the correlation of the results of animal experiments with the observations on human subjects, we believe that the burden of proof now rests on those who maintain the undesirability of the use of this form of therapy. Its actual practical value in particular clinical conditions will, of course, be determined only by more extensive clinical experience.

It must be admitted that the mechanism of toxicity is still unexplained. Our findings do not agree entirely with those of Ham and Lewis¹⁸. It is possible that the dose of approximately 600,000 per kg per day or more, which these observers administered to rats, was a factor in producing a different type of lesion. Up to the present time conceptions of the physiology of vitamin D have perhaps been too circumscribed because of its striking effect on calcium metabolism. That the thyroid plays an important part in the action of vitamin D is indicated by the results of another investigation¹⁷.

Also, it appears that the pathologic effects are greatly accentuated in a hypothyroid state. This *may* be an important factor in the variability in sensitivity to intoxication.

The results obtained by Gelfan¹⁸ on isolated frog muscle suggest that vitamin D exercises a catalytic effect in peripheral tissues. If this should be confirmed, it might serve as a forward step in explaining the injury to isolated cells in peripheral tissues. It is conceivable that the metabolism of individual cells might be accentuated to such a point as to result in the disintegration of the cells themselves. We have not been able to recognize the cellular changes preliminary to disintegration so that we can offer no explanation of the actual nature of this process.

SUMMARY AND CONCLUSIONS

1 Observations on 64 dogs and 773 human subjects receiving massive doses of vitamin D have been made and data recorded as to dose per unit of body weight, and on the nature of the process of intoxication.

2 Both human subjects and dogs generally survive the administration of 20,000 units per kilogram per day for indefinite periods without intoxication.

3 Hypervitaminosis D first produces cell injury followed by calcium deposition. This process is reversible and reparable if administration is discontinued promptly.

4 Intoxication for short periods does not result in any permanent injury that can be recognized by the methods employed in this investigation.

ADDENDUM After this manuscript was written there came to our attention a very comprehensive study by Cowdry and Scott¹⁹ on normal monkeys under treatment with vitamin D in which it was suggested that pathological changes may occur in tissues without clinical symptoms. However it was also suggested that there might be a species peculiarity.

THE DIETETIC TREATMENT OF CONSTIPATION WITH SPECIAL REFERENCE TO FOOD FIBER

By JOHN L. KANTOR, Ph D, M D, and LENNA F. COOPER, M A,
New York, N. Y.

THE non-cathartic treatment of constipation includes, among other recognized measures, treatment by diet (vegetables, cereals, fruits, fats and water), and treatment by artificial bulk producers (mineral oil, agar, bassorin, psyllium seed, cellulose and bran). In recent years the artificial products have dominated the literature and have perhaps unduly impressed the mind of the practitioner. Useful as they may be to meet temporary conditions, it is now becoming realized that these substances cannot be employed indefinitely without the possibility of some interference with nutrition (Bastedo,² Morgan¹²).

It therefore seems timely to refocus attention on the diet—for this after all must always remain the mainstay in treatment. Perhaps the most striking finding in examining the scientific basis for our clinical procedures in this connection is the fact that apparently no important quantitative studies on humans have made much impression on the clinical literature between the time of Rubner¹⁴ in the eighteen-eighties to the recent publications of such physiologists as Rose,¹³ Cowgill^{8,9} and their associates. Working with human subjects, as well as with experimental animals, these observers confirmed the fundamental axiom that there exists a quantitative relation between the amount of crude fiber ingested and the laxative result. Cowgill especially has clearly stated the criteria of laxation, has laid down the general procedure for the study of laxative substances on a fiber-equivalent basis, and has suggested that for normal men the physiologic fiber minimum for adequate laxation corresponds to a daily intake of 90 to 100 milligrams of fiber per kilogram of body weight. This worker confined his attention to the use of wheat bran as a laxative. In five constipated subjects two were relieved by a diet rich in fruits and vegetables, but three others required the addition of bran for comfort. It might be added that in none of the recent work is there any attempt to standardize the intake of fibrous foodstuffs in general, nor to compare the relative value of one of these articles with another.

In view of our thesis that constipation should be treated as thoroughly as possible by diet before calling upon artificial products for assistance, it would appear desirable for the physician to have a sound basis of precise information. In this regard, however, the current American books on diet are not very helpful. For even an approximate statement of the quantitative employment of diet in the treatment of constipation one must go back to von Noorden¹⁵. This author advocated the use of a bulky diet containing

* Received for publication June 29, 1936

a daily intake of 300 to 500 gm (10 to 17 slices) of whole wheat bread, 80 to 100 gm of dried legumes (peas, beans, lentils) in the form of thick soup, and 10 to 15 large prunes (about 100 to 150 gm according to our standards) This diet gave von Noorden excellent results in Germany for over 25 years However, it is not equally practical for use in this country because of the persistent trend away from breadstuffs and legumes

For this reason, and because of their recognized superior laxative properties, fruits were selected as the subject of our study Prunes, apples and bananas were chosen because of their general attractiveness and availability and also for the following specific reasons Prunes, because of their ancient repute as cathartics and the recent discovery (Emerson¹⁰) that they contain an active principle similar to di-hydroxy-phenyl isatin, related to the commercial "isacen", apples, because of their wide popularity as "bowel regulators", and bananas, because of the possibility that their smooth texture might make them particularly useful in spastic or irritated colons

This experiment therefore was planned to determine the relative usefulness of these three fruits on a fiber-equivalent basis The prunes, apples and bananas used in our study possessed a fiber content of 1.9 per cent, 1.4 per cent and 0.6 per cent respectively, representing a ratio of 3 : 2 : 1 *

METHODS

The subjects selected for this study were nine hospital dietitians They were in good general health and carried on their regular work throughout the course of the experiment On the basis of their bowel function the subjects were classed as follows Regular, three subjects (5, 7, 8), irritable, two subjects (1, 3), constipated, four subjects (2, 4, 6, 9)

All four constipated subjects showed low basal metabolic rates (exceeding minus 10), on at least one occasion This finding, it must be confessed, surprised us and suggests an intimate relation between an individual bowel function and the thyroid secretion It also lends emphasis to what T R Brown⁴ has long maintained, namely, that constipation may in many instances be due to a "forme fruste" of myxedema

The experiment was divided into eight periods of at least nine days each as follows

Period I Preliminary Diet uncontrolled

Period II Low Fiber Basal Fiber content 33 mg per kg from miscellaneous sources

Period III First Banana Fiber content 33 mg per kg all from bananas

Period IV Prune "Low Fiber Basal" plus 33 mg fiber per kg from prunes, making a total of 66 mg fiber per kg

Period V Second Banana "Low Fiber Basal" plus 33 mg fiber per kg from bananas, making a total of 66 mg fiber per kg

* The figures for prunes and apples were obtained from actual laboratory analysis of fruit used in the experiment The fiber content of bananas was obtained from Circular No 50, U S Dept of Agriculture⁶

Period VI Apple "Low Fiber Basal" plus 33 mg fiber per kg from apples, making a total of 66 mg fiber per kg

Period VII Medium Fiber Basal Fiber content 66 mg per kg from miscellaneous sources (see table 1)

Period VIII Third Banana "Medium Fiber Basal" plus 33 mg fiber per kg from bananas, making a total of 99 mg fiber per kg (see table 2)

Except for Period I, which served as a control, the diets were weighed and so arranged as to fulfill the basic requirements as to caloric value, relative proportions of carbohydrate, protein and fat, and total fluid intake for the ideal weight for each subject. The fiber content was controlled throughout except in the first period, being modified from time to time according to the needs of the experiment. It also was calculated for the ideal weight for each subject. Whenever changes in fiber content were made, the caloric and basic factors were maintained by manipulating the fiber-free foods (e.g. butter, meat, milk, fruit juices) in the diet (see tables 1 and 2).

The periods were marked off from each other by the ingestion of a capsule containing approximately $7\frac{1}{2}$ grains of caimine or, if menstruation had to be considered, the same bulk of charcoal. A short basal period of three days was interpolated between successive experimental periods to allow for hangover effects. In addition the first two days of each period were disregarded for calculating laxation rates in order to discount any possible latent interval. In other words only the last seven days of each experimental period were used for the final statistics despite the fact that at least 12 days elapsed from the end of one experimental period to the end of another.

The laxation (number of stools) was recorded for each day of every period by each subject, the participants also noting the ease of bowel evacuation (subjective impression) and the character of the stools. In this paper the laxation is expressed in terms of stools per week per person.

The total colon emptying time was observed roentgenographically in five of the subjects during the first six periods of the experiment. This was accomplished by following the progress of a standard barium meal through the colon and rectum until all traces of barium were spontaneously eliminated. The opaque meal was not administered until the third or fourth day of each experimental period by which time the carmine or charcoal had been identified in the feces.

The normal total colon emptying time was determined from a review of 844 private patients previously published by one of us¹¹. It was found to be 72 hours. In the preliminary (control) period only one subject showed an emptying time of 72 hours. Of the rest, three emptied in 96 hours and one in 120 hours. These figures therefore furnished the base line for the present experiment, each subject being compared throughout with her original figures.

The weight of the stools was determined in the last two periods by actual measurement immediately after passage. This served as an additional check on laxation since it was found that the increased number of stools did not always mean that a laxative effect was being produced.

EXPERIMENTAL RESULTS

Period I (Preliminary) The diet was not controlled, each subject eating what she pleased but recording the following data: ideal weight (for height, age, sex), fiber intake per day, individual laxation rate.

The daily fiber intake was estimated from the individual records and was found to vary from 44 to 97 mg per kg. The average was 68 mg., or two-thirds of Cowgill's physiologic minimum. The group laxation (seven day total for nine subjects) was 73. The laxation averaged 8.1 stools per individual per week. This period was considered typical ("normal") by all but one participant, despite the fact that the extremes of laxation varied from a maximum of 13 to a minimum of three. The total colon emptying time averaged 96 hours, with one subject taking 72 hours (ideal), one, 120 hours, and the remaining three, 96 hours for evacuation of the standard opaque meal.

There was no absolute correlation between the fiber intake, laxation, and colon emptying time. The best showing was made in the roentgen-ray group by subject 1 with a fiber average of 71 mg per kg, laxation of 9, and colon emptying time of 72 hours. Subject 6 (not roentgen-rayed) took about the same amount of fiber, 75 mg, but had a laxation of 3. Subject 2 who felt more constipated than usual in this period had a fiber intake of 44 mg, a laxation of 10, but a colon emptying time of 120 hours. Two subjects (7 and 9) took about the same amount of fiber, 90 and 97 mg, respectively, but subject 7 had a laxation of 12 and subject 9 a laxation of 6 in this period. The four constipated individuals took 44, 55, 75, and 97 mg of fiber respectively. The highest intake was associated with a laxation of 6

Period II (Low Fiber Basal) The object of this period was to determine whether constipation could be produced at will by diminishing the fiber content of the diet to one-third the physiologic fiber minimum. Maintaining the energy and other basic requirements, the diet was prepared to supply a fiber content of 33 mg per kg of ideal weight—a fiber level which, according to Cowgill, should produce constipation. Such a result was indeed secured, the group laxation dropping to 58, the individual laxation to 64, and the colon emptying time increasing to 130 hours.

Every subject felt "constipated," the maximum individual laxation being 8, the minimum 1. The colon emptying time of subject 1 remained at 72 hours with 8 stools, but that of subject 2, also associated with a laxation of 8, was 168 hours. The colon emptying time of subject 6 (1 stool per week) was not studied because she was not in the roentgen-ray group, but was estimated as at least 240 hours.

Period III (Fruit Banana) This period was introduced to determine whether bananas contained any hitherto unknown laxative quality other than their fiber (and other carbohydrate) content. In order to test this possibility, the 33 mg of fiber (from miscellaneous sources) of the basal period were completely replaced by the same amount of banana fiber. In other words, all the fiber in this period was derived from banana exclusively. It took approximately three bananas (315 to 325 gm) to supply this amount of fiber. The group laxation was 60, the individual 66, the colon emptying time 81. In short, all the findings remained the same as in the basal period except for acceleration of the colon emptying time. It should be noted in this connection that five of the nine subjects menstruated during this period. Since laxation is usually increased by this function, the acceleration of the colon emptying time should probably be considerably discounted.

In view of the above findings, it was concluded that there is no evidence that bananas possess any special cathartic value in addition to that of their fiber (and other carbohydrate) content.

The diets for the next three periods were constructed according to a uniform plan. The basal diet contained 33 mg per kg of fiber derived from miscellaneous sources. To this were added 33 mg per kg of additional fiber, derived respectively from prunes, bananas and apples, according to the fruit studied in each period. The total fiber content of the diet was 66 mg per kg. It was decided not to exceed this level because reasonably satisfactory laxation had been produced in this group by a similar amount of fiber derived from miscellaneous sources (see Period I). Besides, it was thought that the ingestion of more than 33 mg per kg of fiber from a single fruit source would so overbalance the diet as to make it impractical for everyday use. Thus, for example, 66 mg of fiber per kg would mean 6 bananas per day, or 40 prunes, or 2½ apples.

Period IV (Prune) Approximately 20 small California prunes (100 gm edible portion) a day were required to yield 33 mg per kg of fiber.

The group laxation was 70, the individual laxation averaged 77 stools per week per person, the colon emptying time averaged 91 hours. Five subjects found prunes the most laxative of the three fruits tested. Two found them second best and two rated them least effective.

Period V (Second Banana) The same amount of banana was used as in the first banana period, but this was in addition to the 33 mg from miscellaneous sources of fiber. The group laxation was 62, the individual laxation averaged 68 stools per week per person, and the colon emptying time averaged 98 hours. One subject found bananas the most laxative fruit, three subjects gave it second place, and five subjects found it least effective.

Period VI (Apple) A daily average of $1\frac{1}{4}$ to $1\frac{1}{2}$ cored and peeled "Delicious" apples weighing 140 gm and served raw was required to yield 33 mg of fiber. The group laxation was 55, individual laxation averaged 61 stools per week per person, and colon emptying time averaged 115 hours. Three subjects found this the most laxative period, two found it the most constipating. The remaining four found it occupying an intermediate position, more laxative than bananas, less than prunes.

The next two periods were designed to determine the effect of a diet containing the physiologic fiber minimum (99 mg) in which one-third of the fiber was derived from fruit and two-thirds from miscellaneous sources. The first of these periods (Period VII) served as a control and contained 66 mg of fiber from mixed sources. Banana was the source of the fruit fiber used in the last phase of the experiment (Period VIII).

Laxation was determined not only by recording the daily number of stools per subject as heretofore, but in addition by weighing the fresh stools immediately after passage. The colon emptying time was not determined roentgenologically. Each period was of nine days' duration. As heretofore the periods were marked off by carmine or charcoal and only the last seven days in each case were used in the final calculations. Five of the nine subjects who volunteered for the first six periods were used in this study.

Period VII (Medium Fiber Basal) (see table 1) The diet contained 66 mg of fiber per kg for each subject, derived from miscellaneous sources. This period served as control to the final period.

Laxation was fairly normal for the period, averaging 35 stools for the group of five, or 7 stools per person per week. The weight of the stools averaged 670.6 gm per person per week.

Period VIII (Third Banana) (see table 2) The diet was the same as in Period VII, plus 33 mg of fiber derived from an average of three bananas daily, making a total fiber content of 99 mg per kg for each subject. As heretofore throughout the experiment this change was effected without altering the caloric or other values of the diet.

Laxation was increased to a group level of 38 stools, an average of 7.6

stools per person per week. The weight of the stools increased to 771.2 gm per person per week. Of five subjects tested, three showed a definite increase in laxation, and one showed practically no change. The fifth subject was apparently constipated by the banana diet. Among those whose laxation was increased was subject 6, the most constipated individual in the group. Her laxation rose from 3 in Period VII to 5 in Period VIII, and the stool weight from 385 to 740. Period VIII was rated by her equal to the apple period which had heretofore given the best laxation.

From the above experience it was concluded that the addition of approximately three bananas a day to an "average" diet (66 mg of fiber from miscellaneous sources) is moderately laxative. The effect can be expressed as an increase in the number of stools by 0.6 per subject per week, and an increase in the weight of the stools by 100 gm per subject per week.

EXPERIMENTAL CONCLUSIONS (see table 3)

According to the average laxation and colon emptying time, the laxative power of the three fruits when tested on a strictly fiber-equivalent basis (66 mg per kg) may be rated as follows. First, prunes with laxation of 7.7 and colon emptying time of 91 hours, second, bananas, with laxation of 6.8 and colon emptying time of 98 hours, third, apples, with laxation of 6.1 and colon emptying time of 115 hours.

TABLE III
Laxative Effect of Prunes, Apples, Bananas

Experimental Period	Total Stools per Week	Laxation per Person per Week	Colon Emptying Time Hours	Stool Weight Grams
I Preliminary	73	8.1	96	—
II First Basal	58	6.4	130	—
III First Banana	60	6.6	81	—
IV Prune	70	7.7	91	—
V Second Banana	62	6.8	98	—
VI Apple	55	6.1	115	—
VII Second Basal	35*	7.0	—	670.6
VIII Third Banana	38*	7.6	—	771.2

* Five subjects

On the other hand, the number of stools was not always an accurate guide to the laxative effect because some subjects felt that as they became more constipated they required more efforts to eliminate the same or smaller bulk of stool than they would if the feces were softer. It is for this reason, for example, that subject 9 rated apples (six stools per week) above bananas (eight stools per week).

Accordingly, if subjective criteria only are considered, the fruits rank as follows. Prunes gave the best laxation in five subjects, apples in three,

bananas in one, and conversely, bananas gave the poorest laxation in five subjects, apples in two and prunes in one

However, bananas cannot be considered constipating since in most cases they increased laxation when added to an "average" diet (total fiber 99 mg per kg). Similar results are reported by Bergeim³ who found that two bananas taken before lunch and dinner and at bedtime produced daily large soft stools in three constipated subjects. In fact, owing to their smooth texture and relatively low fiber content, bananas may prove of special value in constipation associated with an irritable colon (see below)

The effect on the individuals according to their classification in terms of original bowel function may be described as follows. The two subjects with irritable colon (1 and 3) tolerated the experiment without developing diarrhea at any of the fruit periods. One of these sensitive subjects preferred the effect of bananas to that of both the other fruits tested. The three subjects classed as "regular" all preferred the effect of prunes. Of the four constipated subjects three preferred apples and one prunes. The most constipated individual (6) rated apples first, bananas second and prunes last on the basis of subjective impression.

It is probable that the simultaneous employment of several sources of fiber is superior to the use of a single variety. This is suggested by the fact that laxation was freer in the preliminary period of our experiment when the sources of fiber were freely chosen than in most of the subsequent periods when the sources were restricted.

CLINICAL APPLICATIONS

There is no reason why the diet for constipation should not be planned with the same precision that one prescribes a diet for diabetes or for obesity. In other words the physician should be able to think in quantitative terms about fiber as he does about calories, carbohydrates, fats or proteins. Cowgill's concept of the physiologic fiber minimum should receive due recognition. The fiber content of the more important fruits and vegetables and cereals should be made more generally available to the physician.

In the accompanying tables (tables 4, 5 and 6) the fiber component is shown not only as a percentage but as it occurs in the average serving portion. By using these data the physician is now equipped to construct a diet for constipation on a quantitative basis.

According to the Cowgill standard of 100 mg of fiber per kg body weight, a man of 70 kg will normally require 7 gm of fiber daily, a woman of 55 kg will need 5.5 gm. In order to obtain this total, selection may be made in approximately equal portions, from each of the three classes of fibrous foodstuffs—fruits, vegetables and cereals. The exact procedure may be outlined as follows, bearing in mind that only bland foods should be selected at the beginning of treatment.

- 1 From the list of fruits, three varieties may be chosen, preferably one

TABLE IV
Fiber Content of Cereals and Cereal Products
(Based on Edible Portion and Average Servings)

Cereals	Amount of Average Serving		Per Cent of Fiber	Grams of Fiber per Average Serving
	Measure	Weight in Grams		
Bran, prepared	$\frac{1}{3}$ cup	20	8.5	1.70
Bran flakes	$\frac{2}{3}$ cup	30	5.1	1.53*
Corn flakes	1 cup	25	2	.05
Corn meal	$\frac{1}{2}$ cup, cooked	20 (dry)	2	.04
Cream of wheat	$\frac{1}{2}$ cup, cooked	20 (dry)	2	.04
Farina	$\frac{1}{2}$ cup, cooked	20 (dry)	2	.04
Grape nuts	$\frac{1}{4}$ cup	30	2.4	.72†
Hominy grits	$\frac{1}{2}$ cup, cooked	20 (dry)	4	.08
Noodles	$\frac{1}{2}$ cup, cooked	25 (dry)	4	.10
Oats, rolled	$\frac{1}{2}$ cup, cooked	20 (dry)	9	.18
Puffed rice	1 cup	15	1	.01
Puffed wheat	1 cup	15	1.6	.16
Rice Krispies	1 cup	30	3	.09*
Ry-Krisp	2	15	1.3	.20
Shredded wheat biscuit	1 biscuit	30	2.6	.78
Spaghetti	$\frac{1}{2}$ cup, cooked	25 (dry)	4	.10
Wheatena	$\frac{1}{2}$ cup, cooked	20 (dry)	6	.12
Wheat flakes, toasted	$\frac{2}{3}$ cup	30	1.8	.54*
Wheat krumbles	$\frac{1}{2}$ cup	30	1.9	.57
Bread				
Crackers				
Graham	2 large	15	1.5	.23
Soda	2 large	15	3	.05
Rye, whole	1 slice	30	1.2	.36
White	1 slice	30	5	.15
Whole wheat	1 slice	30	1.2	.36

The above figures for cooked cereals are based on the weight of the raw material in an average serving, the average serving being a half cup.

Unless otherwise stated, the per cent of fiber was obtained from Analyses of Common Foods Bulletin No. 373, Connecticut Agricultural Experiment Station, 1934.⁷

* Fiber value obtained from Research Laboratories, Kellogg Co., Battle Creek, Mich.

† Fiber value obtained from General Foods Corporation, New York.

for each meal. Assuming that apples, prunes and bananas are taken, it will be noted that the fiber in three average portions adds up to 2.2 gm (1.0 gm plus 0.6 gm plus 0.6 gm).

2. Four vegetables should be selected including one serving of potato (0.4 gm). If to this are added string beans (1.05 gm), spinach (0.45 gm) and asparagus (0.35 gm), the total from this source becomes 2.25 gm.

3. For the cereal foodstuffs one whole grain cereal such as shredded wheat (0.78 gm) with perhaps a slice of whole wheat bread (0.36 gm) should be taken for breakfast. At each of the other two meals two slices of bread (0.72 gm) may be used. This brings up the total for this group to 2.58 gm. For some of the bread other cereal products such as noodles, cake, pastry and certain puddings may be substituted.

TABLE V
Fiber Content of Vegetables
(Based on Edible Portion and Average Servings)

	Amount of Average Serving		Per Cent of Fiber	Grams of Fiber per Average Serving
	Measure	Weight in Grams		
Artichokes (French)	1 medium	30	3 2	96
Asparagus	6 med stalks	50	7	35
Beans				
Lima (fresh)	$\frac{1}{2}$ cup, cooked	60	1 5	90
Snap (string)	$\frac{1}{2}$ cup, cooked	75	1 4	1 05
Beets (common red)	$\frac{1}{2}$ cup, sliced	75	9	68
Beet greens	$\frac{1}{2}$ cup, cooked	75	1 4	1 05
Broccoli	1 med stalk	100	1 3	1 30
Brussel sprouts	$\frac{2}{3}$ cup	100	1 3	1 30
Cabbage	$\frac{1}{2}$ cup, raw	50	1 0	50
Carrots	$\frac{1}{2}$ cup, cooked	75	1 1	76
Cauliflower	$\frac{1}{2}$ cup, cooked	75	9	68
Celery	$\frac{1}{4}$ med stalk	40	7	28
Corn (sweet)	$\frac{1}{2}$ cup, cooked	75	8	60
Cucumbers	$\frac{1}{3}$ medium	30	5	15
Eggplant	$\frac{1}{2}$ cup, cooked	75	9	68
Kale (leaves)	$\frac{1}{2}$ cup, cooked	75	1 2	90
Kohlrabi	$\frac{1}{2}$ cup, cooked	75	1 1	76
Lettuce	$\frac{1}{4}$ med head	75	6	45
Mushrooms	$\frac{1}{2}$ cup, cooked	50	9	45
Mustard greens	$\frac{1}{2}$ cup, cooked	75	8	60
Onions	$\frac{1}{2}$ cup, cooked	75	8	60
Onions (young green)	6-8 small	50	1 8	90
Parsnips	$\frac{1}{2}$ cup, cooked	75	2 2	1 65
Peas (green shelled)	$\frac{1}{2}$ cup, cooked	75	2 2	1 65
Potatoes	$\frac{1}{2}$ cup, diced	100	4	40
Radishes	3-4 medium	30	7	21
Spinach	$\frac{1}{2}$ cup, cooked	75	6	45
Squash (summer)	$\frac{1}{8}$ squash, 5 in diam	100	5	50
Squash (winter)	2 X 2 X 1 in	100	1 4	1 40
Sweet potatoes	1 small	100	1 0	1 00
Tomatoes (red)	1 medium	100	6	60
Turnips	$\frac{1}{2}$ cup, cooked	50	1 1	55

The above figures are based on the raw weight of vegetables contained in an average cooked serving, which is a scant half cup. The percentage of fiber was obtained from Proximate Composition of Fresh Vegetables, Circular No 146, U S Department of Agriculture, by Chatfield and Adams, 1931.⁵

The foods used in the above example will give a daily total of 7.03 gm of fiber. It is to be observed that in planning this type of diet slight changes may have to be made in the patient's bill of fare: (1) more attention must be paid to the choice of fruits, vegetables and cereals, (2) fruits will usually have to be substituted for the common non-fibrous desserts, such as ice cream, custard and gelatin preparations.

As regards the particular fibrous foodstuffs to be recommended, it need hardly be pointed out that clinical judgment should be the guide in practice. Common experience as well as individual idiosyncrasies should always be respected. Just because a certain fruit or vegetable possesses much fiber is

TABLE VI
Fiber Content of Fruits
(Based on Edible Portion and Average Servings)

	Amount of Average Serving		Per Cent of Fiber	Grams of Fiber per Average Serving
	Measure	Weight in Grams

* Calculated from the fresh fruit

† Fiber value obtained from California Dried Fruit Research Institute, San Francisco

not in itself a sufficient reason for its recommendation. It is not very likely, for example, that patients able to tolerate corn, cabbage, baked beans and rough berries will consult a physician for the relief of constipation. Von Noorden was very careful to point out that only a few of the simpler fibrous foods should be used at the beginning of treatment, and that these should be continued in full doses until regular function is well established. It is only after this is accomplished that more stimulating foods may be added. Every effort should be made to avoid colic, distention and other evidences of irritation, *since the resulting spasm may serve to increase the fecal stasis*.

In any regimen for the treatment of constipation adequate water intake is essential to supply the means by which the fruit and vegetable pectins and galactans soften the feces. A daily minimum of four to six glasses (1000 to 1500 cc) is necessary, water taken immediately on arising being espe-

cially beneficial. An increased fat intake is also desirable but this has limitations in practice. Its chief application is in undernourished subjects where it is best taken in the form of butter, in amounts up to $\frac{1}{4}$ lb daily. Olive oil (1 oz. two to three times a day) as such, or as "cocktail" with tomato juice or orange juice, is acceptable to some people.

A few suggestions in the practical use of fruits may be of interest. Our experience indicates that the addition of fruit in the amount of 33 mg of fiber per kg. to an "average" diet, containing approximately 66 mg per kg. of fiber from other sources, should relieve constipation in many, if not most, simple cases. As already explained, this amounts, for an average man, to a little over 7 gm of fiber per day. In obstinate cases of constipation, however, the amount of fruit fiber may have to be increased considerably, additional fruit being taken between meals if necessary.

The discovery of an active principle in prunes suggests that certain fruits may possess special cathartic properties in addition to their fiber-acid-sugar content. However, our experiment fails to show outstanding superiority for prunes because only five out of our nine subjects rated them first in laxation and two reported them least effective as compared with the other two fruits studied. In any event further investigation in this direction is desirable. Prune juice is said to contain the same active principle as the whole fruit. It may therefore be more widely used as a breakfast drink either instead of or in addition to the citrous fruit juices.

Cooked apples may be substituted for the raw. Bananas may be served in any way desired, but if eaten raw they must be ripe since the unconverted starch may cause "indigestion". The criteria of ripeness are that the skin is entirely yellow and generously flecked with brown and that the pulp has softened. At this stage practically all the starch is converted into easily digested fruit sugars. Attention should be called to the fact that in the ripening process the tip of the fruit is the last portion to show traces of green color. It may therefore be used as an indicator of fitness for consumption. Obviously, it is not correct to cut off the green portion as is done in some households, and offer the rest of the unripe fruit to be eaten.

SUMMARY AND CONCLUSIONS

1. An adequate fiber intake is important in the dietetic treatment of constipation. Fiber is supplied by three classes of foodstuffs,—fruits, vegetables and cereals.

2. The relative laxative value of typical fruits was studied in human subjects on a fiber-equivalent basis. Previous work showing that the laxative effect of a diet depends largely on its fiber content was confirmed and the value of such typical fruits was demonstrated. Although prunes were found to be generally more laxative than apples or bananas, yet each of the latter proved more effective in individual cases. There is reason to believe that bananas are of special value in constipation associated with colonic instability.

3 Tables are furnished showing the fiber content of the common fruits, vegetables, and cereals, in per cent by weight and in amount per portion. With the aid of such data constipation diets may be planned on a quantitative basis.

4 In the selection of fibrous foods only bland articles should be used at the beginning of treatment because rough foodstuffs may provoke bowel irritation with resulting spasm and increase in constipation.

5 For the relief of many, if not most cases of simple constipation ordinary servings of fruit should be taken three times daily, preferably as desserts. It is suggested that the daily use of approximately 2 gm of fruit fiber in addition to the "average" diet, containing four vegetables and some whole grain foodstuffs, suffices in such cases. This amount would be supplied for example by six prunes, one banana and one medium-sized apple. In more obstinate cases proportionately larger intake would be needed.

THE OCCURRENCE OF CORONARY THROMBOSIS IN YOUNG INDIVIDUALS¹

By THOMAS M. DURANT, M.D., *Philadelphia, Pennsylvania*

CORONARY thrombosis in young adults has been generally considered of rare occurrence. There is much statistical evidence to support this opinion. Levine and Brown¹ in their classical monograph on coronary thrombosis reported 145 cases with an average age of 57.8 years. There were only three cases in this group under the age of 40, and none was younger than 35. The report of Connor and Holt² included 287 cases, 20 being under 40 years of age and only two under 35. Many other articles on this subject give similar statistical data as to age distribution.

Recently, however, reports have appeared in the literature indicating that coronary thrombosis is not as strictly limited to age periods beyond 40 as was previously supposed. Leary,³ in an interesting study dealing with the pathology of coronary arteriosclerosis and its relationship to the cholesterol metabolism, includes reports on the postmortem findings in eight cases of coronary thrombosis occurring in individuals under 40 years of age, five of whom were under 35. White⁴ has recently reviewed 14 cases of coronary thrombosis in individuals under the age of 40. Smith and Bartels⁵ reviewed isolated case reports in the literature and were able to collect 20 proved cases in patients 40 years of age or younger, and to this group they have added two cases of their own in which the ages of the patients were 35 and 36 years respectively.

That coronary thrombosis may occur with surprising frequency in younger individuals is further emphasized by the recent high incidence of such an occurrence at the University Hospital, Ann Arbor, Michigan. Seven cases occurring in patients 35 years of age or under have been observed in this clinic during the four year period from 1931 to 1935. This group constitutes 6.1 per cent of the 114 proved cases of coronary thrombosis recorded in the files of the University Hospital.

CASE REPORTS

Case 1 L. G., a Jewish male student of 23 years, had experienced, during a period of 10 weeks prior to his admission to the University Hospital, three attacks of severe, grasping, substernal pain, radiating to the left arm, and relieved only by narcotics. Prostration, profuse perspiration and dyspnea were associated with these attacks. His past history and family history were negative. The physical examination on admission was negative. The blood pressure was systolic 122 mm. Hg and diastolic 70. The routine urine and blood examinations, including the Kahn reaction, were negative. The standard electrocardiogram taken shortly after admission is reproduced in figure 1 A. The large Q-wave with a small R-wave in Lead I,

¹ Received for publication June 29, 1936.

C—Case 3, standard electrocardiogram showing large Q-waves in Lead I and inverted T-waves in Leads I and II
D—Case 4, standard electrocardiogram, taken within a few hours of the onset of symptoms of coronary occlusion, showing large Q-waves in Leads II and III, depression of the S-T segment in Lead I and elevation of the S-T segment in Leads II and III
E—Case 4, standard electrocardiogram, taken 22 days after acute coronary occlusion, showing large Q-waves and markedly inverted T-waves in Leads II and III

together with the sharply inverted T_1 , confirmed the clinical diagnosis of coronary occlusion, and pointed to an anterior location of the infarct. The precordial electrocardiogram (figure 2) provided evidence of an extensive anterior infarct.

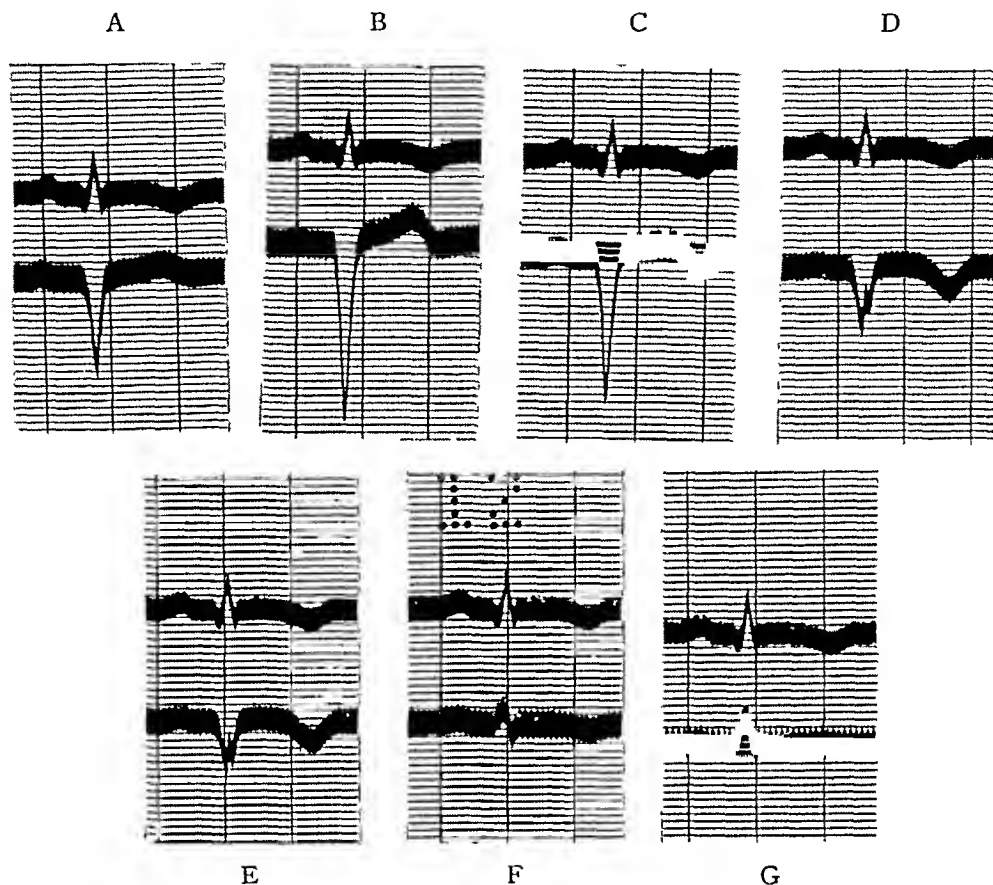

FIG 2 Case 1, precordial electrocardiogram (lower curve) taken simultaneously with standard Lead I (upper curve) according to the method of Wilson, Johnston, Macleod and Barker.⁸ The leads were so connected that relative negativity of the exploring electrode is represented by a downstroke.

- A—5th rib at right edge of sternum
- B—5th rib at left edge of sternum
- C—5th i c s mid-way between sternum and left mid-clavicular line
- D—5th i c s at mid-clavicular line
- E—5th i c s at left nipple line (2 cm to left of D)
- F—6th rib in left anterior axillary line
- G—6th i c s in left mid-axillary line

The normal initial upstroke is absent in A, B, C, D and E, a finding indicative of myocardial infarction. Note also the T-wave changes in C, D and E.

Case 2 G K, a carpenter, aged 33, had been in good health until 10 months before admission when he had begun to notice epigastric soreness and dyspnea brought on by marked exertion and relieved by rest. Six weeks before admission, following a heavy meal, a severe attack of epigastric pain associated with vomiting, dyspnea, and palpitation had necessitated his admission to a hospital where his temperature was found to be 102.6° F and the white blood cell count 21,600. Following this attack, anginal symptoms had been induced by less exertion than previously. The past history and family history were negative. The physical examination on

admission to the University Hospital was entirely negative. The blood pressure was systolic 115 mm Hg and diastolic 72. The peripheral arteries were soft. The blood Kahn reaction, urine and routine blood examinations were negative. An orthodiagram showed the heart to be normal in size. There was slight widening of the base of the aorta. The standard electrocardiogram (figure 1 B) showed a large Q-wave in Lead I and sharply inverted T-waves in Leads I and II. These findings were considered diagnostic of an anterior wall infarct. The precordial electrocardiogram (figure 3) confirmed this diagnosis and demonstrated the extensive distribution of the area of infarction.

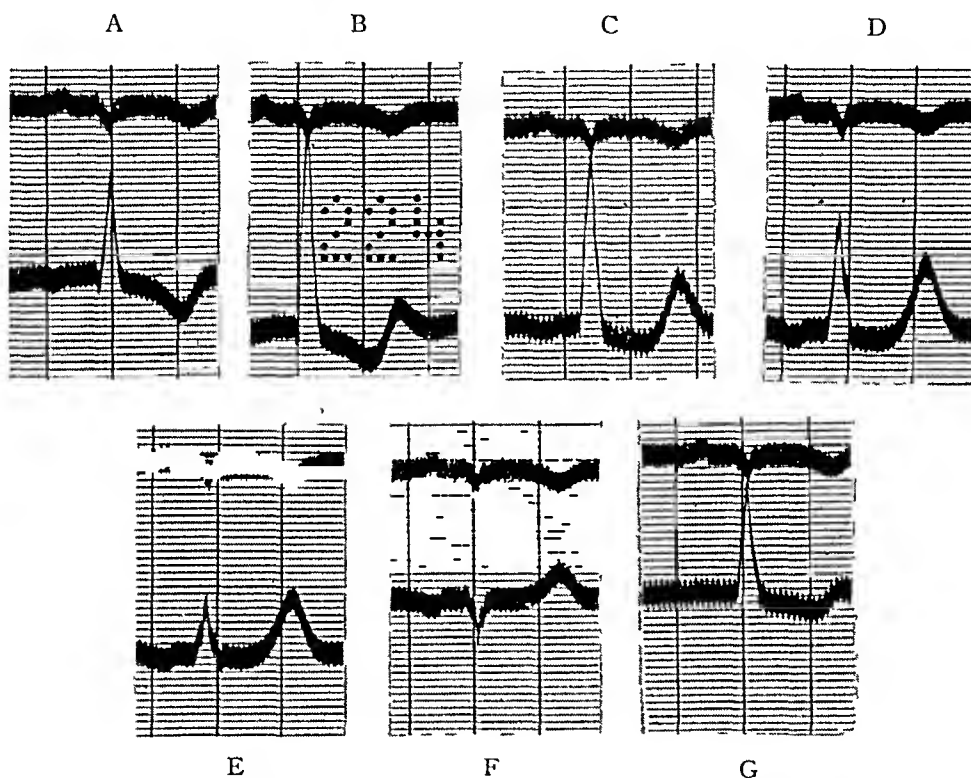

FIG 3 *Case 2*, precordial electrocardiogram taken in the same manner as in case 1 (figure 2) except that the leads were so connected that relative negativity of the exploring electrode is represented by an upstroke.

A—5th rib at right edge of sternum

B—5th rib at left edge of sternum

C—5th ICS mid-way from sternum to mid-clavicular line

D—5th ICS in left mid-clavicular line

E—6th rib, left anterior axillary line

F—7th rib, left mid-axillary line

G—3d rib, left mid-clavicular line

The normal initial downstroke is absent in C, D, E and G, a finding indicative of myocardial infarction. Note also the abnormal T-waves in C, D, E and F.

The patient was discharged greatly improved after a six weeks' period of bed rest. No subsequent information is available.

Case 3 J H, a tool grinder, aged 31 years, had noted mild precordial pain on exertion or following excessive drinking over a period of two years. Two weeks before admission, he had experienced an attack of severe precordial pain radiating to the neck and down the left arm. A second attack occurred four days later and

was associated with fever, palpitation and dyspnea. The past history was negative except for three attacks of gonorrhea. He denied luetic infection. He had been married 13 years and had one child living and well. There had been no miscarriages or still-births. He had been a heavy drinker and had used tobacco to excess. The family history was negative. The physical examination was entirely negative. The blood pressure was systolic 120 mm Hg and diastolic 70. The peripheral arteries were soft. The retinal vessels showed no abnormalities. The blood Kahn reaction, urine and routine blood examinations were negative. The standard electrocardiogram (figure 1 C), a typical curve of the Q_1T_1 type, confirmed the clinical diagnosis of coronary occlusion, as did the precordial electrocardiogram, which demonstrated a large anterior infarct.

Case 4 R M, an auto mechanic, aged 35 years, had been in good health until one and one-half years before admission to the hospital when he had experienced severe precordial pain of six hours' duration. Except for some cardiac irregularity he had felt well following this attack until five weeks before admission. At this time another attack of severe precordial pain occurred and lasted for nine hours. Following this second attack, the patient had been unable to return to work because of dyspnea and precordial discomfort induced by exertion. The past history was negative. The family history was incomplete. Physical examination showed marked cardiac enlargement and signs of congestive failure. The blood pressure was 142 mm Hg systolic and 100 diastolic. The blood Kahn reaction, urine and routine blood examinations were negative. A roentgenogram of the chest showed moderate cardiac enlargement and passive congestion of the lungs. The standard electrocardiogram showed a large Q-wave and a small R deflection in Lead I with a sharply inverted T_1 , findings indicative of infarction of the anterior wall of the heart. Following a period of treatment, the patient was discharged and no later information is available.

Case 5 I T, a Jewish male of 33 years, had suffered four attacks of severe, prolonged substernal pain over an eight year period prior to his admission to the hospital. Since the last attack three years previously he had complained of dyspnea on exertion and weakness. He had been a known diabetic since his first attack. The past history and family history were not recorded. Physical examination showed slight enlargement of the heart, but no other cardiac abnormality was noted. The blood pressure was 120 mm Hg systolic and 75 diastolic. The brachial arteries were soft. The remainder of the physical examination was negative. The blood Kahn reaction and routine blood examination were negative. The urine gave a three plus reaction to Benedict's solution, but was otherwise negative. The standard electrocardiogram showed marked left axis deviation with large Q-waves in Lead I. The patient's diabetes was readily controlled on a diet yielding 90 grams of available glucose with 10 units of insulin daily. He was seen nine months later, at which time he reported marked symptomatic improvement. He had had no further chest pain.

Case 6 J K, a 31 year old mechanic, had been well until five months before observation at which time he had begun to experience attacks of epigastric pain associated with dyspnea, nausea and vomiting. The past history was entirely negative. He had been married 11 years and had one child living and well. His wife's first pregnancy had resulted in a miscarriage. The family history was negative. The physical examination on admission revealed pupils that reacted sluggishly to light, but well in accommodation. The heart was enlarged, but was otherwise negative. The blood pressure was 110 mm Hg systolic and 80 diastolic. The liver edge was palpable at the level of the umbilicus and was smooth and tender. The remainder of the examination was negative. The blood Kahn reaction and routine blood examinations were negative. The urine gave a three plus reaction for albumin and contained 15 white blood cells per high power field, and was otherwise negative. A

roentgenogram of the chest showed gross left cardiac enlargement and widening of the base of the aortic arch. The standard electrocardiogram showed high grade intraventricular block (QRS interval 0.13 second), large Q-waves in Lead I, inverted T-waves in Lead I, and large, broad S-waves in Leads II and III. The patient became markedly jaundiced shortly after admission to the hospital and his general condition grew progressively worse. Death occurred in two weeks. Postmortem examination revealed a localized syphilitic arteritis at the mouth of the left coronary artery with a nearly complete occlusion of the anterior descending branch. There was a myocardial infarct at the apex extending up from the apex 9 cm. on the anterior wall and 4 cm. on the posterior wall. Other findings included hemorrhagic infarction of the lungs, nutmeg liver, slight arteriosclerotic nephropathy, and acute exacerbation of chronic passive congestion of all organs. The postmortem blood Kahn reaction was positive.

Case 7 J. W., a 33 year old metal polisher, was admitted to the University Hospital with anasarca of one month's duration. Four abscessed teeth had been removed one month before the onset of the generalized edematous condition. The patient had had whooping cough, diphtheria, tonsillitis, and possibly scarlet fever in childhood. The family history was negative. Physical examination showed considerable pallor. The tonsils were medium sized and did not appear infected. The eye-grounds appeared normal. The cardiac examination was negative. The blood pressure was systolic 190 and diastolic 110. There were signs of fluid at both lung bases and in the abdomen. The legs were edematous. The blood Kahn reaction and routine blood examinations were negative. The urine showed four plus albumin, and several red and white blood cells per high power field, and 10-30 casts per low power field. The blood non-protein-nitrogen was 37.5 mg. per cent. Five days following admission, while having his back rubbed, the patient developed severe substernal pain. This pain lasted five days and was relieved only by morphine. There was considerable dyspnea with the attack. The temperature and white blood cell count were elevated. A series of electrocardiograms showed changes characteristic of infarction of the posterior wall of the heart. Two of the electrocardiograms have been selected and are reproduced in figure 1 D and E. Several months after the attack of coronary occlusion, and while still in the hospital, the patient developed severe pleuritic pain associated with fever. Death occurred one week later. Postmortem examination showed an occlusion of the right coronary artery 3 cm. from its origin. There was extensive infarction of the posterior wall of both ventricles extending into the septum. The lungs showed hemorrhagic purulent pneumonia. There was an early subacute glomerulo-tubular nephritis with lipoidosis of the tubular epithelium.

COMMENT

Coronary occlusion in older individuals is ordinarily the result of degenerative changes associated with advancing age. What factors were responsible for the premature coronary changes in the patients above described is an interesting and important question. Factors of recognized importance are syphilitic infection, hypertension and diabetes. In four of these patients the explanation may be wholly or partly on the basis of one or the other of these factors. In two of them, cases 4 and 7, hypertension undoubtedly played a part in the development of the coronary condition. Diabetes may be held partly responsible for the premature occurrence of severe coronary disease in case 5. In one patient, case 6, syphilitic infection involving the mouth of the left coronary artery was responsible for the oc-

clusion and resultant infarction of the myocardium. The finding of infarction of the myocardium in this patient is emphasized inasmuch as it is a rare complication following the occlusion of an orifice of a coronary artery or stenosis of one or both orifices by the syphilitic process (Von Glahn ⁶).

There remain three patients (cases 1, 2 and 3) in which the etiological factors above mentioned were entirely lacking. The basis for the premature coronary disease in them remains obscure. An attempt has previously been made to explain cases of this type on the basis of an inherited susceptibility to arterial degeneration. Musser and Barton ⁷ have advanced the hypothesis that there are two distinct expressions of coronary disease. One is observed in elderly individuals, representing largely the effect of senescence. The other is said to be observed in younger men with a familial tendency to coronary disease. A review of the family histories in the three cases under consideration reveals no familial tendency.

It is of interest in reviewing the entire group of seven cases to note that all the patients were males, none was overweight, none was engaged in a professional occupation and in none, except the patients with nephritis and syphilis, did infection appear to play a part. Five of the seven patients were engaged in occupations requiring hard labor. Only one patient (case 3) reported having used tobacco to excess.

The mortality of the acute attack of coronary thrombosis in these cases was unusually low. Five of the seven cases survived their attacks by at least six weeks. Subsequent information is not available except in case 5, in which case the first attack had been survived eight years.

SUMMARY

Coronary thrombosis in young adults, although generally considered to be a rare condition, may occur with surprising frequency. Seven cases in patients ranging in age from 22 to 35 are reported.

THE ESTIMATION OF CARDIAC FUNCTION BY SIMPLE CLINICAL METHODS *

By EMANUEL MESSINGER, A B , M D , *St Cloud, Minnesota*

THE problem of determining the functional impairment, or conversely the cardiac reserve of ambulatory cardiac patients has always been a baffling one. Even with the use of all our modern laboratory adjuncts—the fluoroscope, roentgen-ray measurements of the heart, and lastly the electrocardiogram, in addition to all available clinical methods, one is often at a loss to decide just where in the scale of impairment of cardiovascular function a particular patient belongs. This difficulty of course arises chiefly in the case of the strictly ambulatory cardiac patient, since those patients who show evidences of *decompensation* either at rest or after moderate activity all plainly belong to Class III of the American Heart Association's functional classification.

It is in attempting to differentiate between Class I patients, "those with organic heart disease manifesting no significant disability for the ordinary activities," and Class II A patients, "those manifesting ability to perform with slight impairment," and between the latter Class and Class II B patients, "those with considerable impairment of ordinary activity," that one is confronted with many pitfalls. For the criteria on which we are prone to base our differentiation are in the main purely subjective symptoms, and as Libman has so ably pointed out, the sensitivity (and consequently reactivity) of different individuals to noxious and painful stimuli is extremely variable. The use of our recently acquired laboratory adjuncts to cardiac diagnosis often (though certainly not always) helps us to determine objectively to some degree how much actual disease is masked or magnified under a cloud of subjective complaints.

But these measures are usually not available to the average medical examiner, and he must form his judgment as to the cardiac efficiency of his patient solely on the information obtained by his eyes, hands, ears and a critical mind. Yet upon this judgment must be based prognostic determinations as to the insurability of the patient, disability estimates for compensation purposes, and last but not least therapeutic decisions. Shall he tell the stolid unsuspecting laborer before him, in whom he has found a well-defined organic murmur, that he is a "cardiac" and must change his occupation and otherwise lead a restricted and closely regulated life, or shall he casually inform him that the examination has revealed a "slight leak" which is of little importance, and requires him to make little or no change in his mode of living, beyond observing the ordinary precaution of having a

Published with the permission of the Medical Director of the Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the writer

periodic medical examination? The fallibility of basing such decisions merely on the character of the murmur is too evident to require elaboration here. It is the purpose of this paper to show whether, and if so, to how great a degree, the facts elicited on an ordinary clinical physical examination can be relied upon in estimating the degree of cardiac disability in these types of cases. This will be done by showing the amount of correlation existing between certain readily observable clinical data and the evidences of myocardial damage furnished by the laboratory.

The writer is well aware that various and numerous so-called "effort" and "cardiac function" tests have been put forward in the past. Many of these are not suitable in that they do not represent the ordinary activities of the individual's everyday life (such are spirometer, flarimeter, etc.). All of them are deficient in that no two individuals can be expected to exert the same degree of effort in performing the same tasks. One will walk up and down the prescribed number of steps with vigor, another in an ordinary manner, and a third gingerly or lackadaisically. Similarly in hopping tests, in spite of explicit directions, one will barely more than timidly raise his heels off the floor the required number of times, another will more or less closely approximate the "50 hops—3 inches off the floor—at one second intervals," while a third will leap with great abandon as high as he can off the floor until he is abruptly restrained. The writer proposes no new variation of the exercise tests, as he believes the above sources of inaccuracies are in the main unavoidable. However, since a quantitative equality of the amount of exertion in various individuals cannot be attained, we have tried to avoid as much as possible a quantitative comparison of the results. Instead we have stressed the qualitative relations of the cardiorespiratory adjustment to exercise,—that is, not "exactly how much" the pulse and respiration have increased after exercise, but rather "in what manner" the proportion between pulse and respiration has varied after exercise as compared with the proportion before exercise.

Methods In these studies the following technic was closely followed. The patient's pulse and respiration were taken while he was standing at rest. After the patient had been still long enough for stable rates to be established (generally after a wait of 15 to 30 seconds), the cardiac apex rate was counted (with the stethoscope) for 10 seconds, and immediately thereafter (with the stethoscope still on the chest) the respirations were counted for 15 seconds. These short periods of counting were used because experience showed that the maximal rate changes generally occur very rapidly and subside very rapidly. The patient was then asked to hop 50 times (25 times on each foot), and immediately thereafter the pulse and respiratory rates were taken in exactly the same manner. The auscultatory method of counting both the rates was used exclusively as it was found to be more accurate than the palpatory method, and because it did not interfere with the simultaneous observation (on the "second" dial of a watch) of the elapsed time.

intervals, as a visual method would have done. Since all the observations were made by the same examiner, individual differences in the technic were reduced to a minimum. At this point it may be stated that "sitting resting rates" and "rates three minutes after," and in some cases "rates two minutes after" the completion of the exercise were also taken routinely on all cases. These data, however, will not be considered in this study as it was soon found that there were no significant differences in these factors in many cases of even obviously greatly differing functional cardiac capacities. (For example, a case of marked valvular disease with evident functional impairment was quite as apt to show no elevation of the pulse and respiration three minutes after exercise, as was a case with no cardiac lesion.) Although, as hinted above, 50 hops were routinely asked for, in certain cases more or less were required as it was felt that only exercise sufficient to cause manifestly increased respiratory effort would serve to bring out the qualitative differences mentioned in the previous paragraph.

Why were the criteria just indicated, namely, tachypnea and the pulse-respiratory ratio after exercise, chosen to the exclusion of others? Simply because other criteria are not readily measurable from a practical standpoint. This criticism applies to the usually stressed "dyspnea" or "shortness of breath" and equally to "cyanosis" which necessarily must be subjectively estimated by the examiner. The other definite clinical criteria of impaired cardiac function, namely edema, hepatic and pulmonary congestion, marked cardiac irregularities such as fibrillation, and of course extreme dyspnea and cyanosis, as well as characteristic angina, all are found only in cases that offer no problem for functional classification—they all belong definitely in Class II B. Such cases not only do not usually require a cardiac function test for the demonstration of their disability, but actually may be hazardous subjects to put through such an ordeal.

Clinical Material The material on which these studies were made comprised ambulatory out-patients examined by the writer, consecutively, over an 18 months' period (from September 1931 to May 1933), at the Veterans' Facility at Lyons, New Jersey. They were all veterans, being examined in regard to claims for disability compensation, disability allowance, or insurance purposes. The great majority were veterans of the World War, —the remainder veterans of the Spanish American War and allied expeditions. Data for this study were collected on 209 cardiac cases, and on 101 non-cardiac controls. A substantial majority of the patients had been previously examined by other Veterans' Bureau examiners, and in the occasional instance where there existed a significant discrepancy between the findings in the earlier and in the later examinations, no change was made in the diagnosis unless the later findings were confirmed by a consultant examiner (Dr J. E. Maloney). Occasional patients returned for re-examination during the 18 months' period of the study thus permitting a personal checking of the earlier findings. The ages of the patients under

consideration ranged from a minimum of 29 years for the World War veterans to a maximum of 64 years for the Spanish War veterans. Although the clinical impressions which are the result of this study were derived as a result of the observation of all the 209 cardiac cases and the 101 non-cardiac controls, the statistical corroboration of these impressions will be based only on those 65 cases that were worked up completely from a laboratory as well as clinical angle, viz, those cases in which complete electrocardiographic and roentgenological studies were made in addition to the usual routine clinical physical examination and urinalysis. The following table will indicate the pathologic-anatomical division of the material. It will be noted that the completely worked up cases are listed under the heading, "Complete Data Cases."

TABLE I

Key Letters	Pathologico-Anatomical Type	Total Number of Cases	Number of "Complete Data Cases"	Average Age
Rm	Rheumatic heart disease, typical mitral stenosis and regurgitation	52	18	38.5
Ra	Rheumatic heart disease, aortic valvulitis (stenosis or regurgitation or both)	15	4	42.3
Ra and m	Rheumatic heart disease, combined aortic and mitral valvulitis	38	10	35.3
M	Pure mitral regurgitation	26	8	39.9
H	Hypertensive heart disease	41	6	41
A	Arteriosclerotic heart disease	14	6	44.2
L	Luetic heart disease	7	3	36.3
E	Emphysematous heart disease	2	2	53.5
F	"Functional" heart cases	14	5	42.2
	<i>Totals</i>	209	62	
X	Non-cardiac controls	101	3	

It should be explained that Class "M"—"Pure Mitral Regurgitation"—is not to be considered a specific pathological-anatomical group. Undoubtedly a large proportion of these cases correctly belongs under the "Rheumatic" heading. However, since it is impossible to obtain an accurate history with this type of patient, the writer prefers to list only those cases with typical auscultatory and palpatory findings under the rheumatic classification. The "functional" group is also a rather miscellaneous one and includes such diagnosis as "essential tachycardia", "neurocirculatory asthenia", "tachycardia with severe diabetes", "myxedema heart", "alcoholic tachycardia", "pseudo-angina pectoris," etc.

The average age of 90 non-cardiac controls was 38.4 years, and of 54 "Complete Data" cardiac cases—39.5 years.

Results As these studies progressed, the writer began to feel that a triad of clinical signs often appearing after ordinary exercise, could be taken as fairly reliable indices of cardio-respiratory embarrassment, and inferentially,

in those cases in which no respiratory disease or other obvious cause of increased pulse or respiratory rate was detectable, the occurrence of these signs pointed toward the existence of organic heart disease with definitely impaired function. These signs were (1) Tachypnea, an increase of the respiratory rate immediately after exercise to 24 or more per minute, (2) a "paradoxical pulse-respiratory ratio," i.e., a ratio of pulse rate to respiratory rate which is not greater after exercise than before, (3) a diminished pulse lability as indicated by the presence of a pulse/respiratory ratio after exercise which is less than a certain critical minimum norm determined for this age group to be 4.5. The first of these signs was found to be the one most frequently observed, but the third sign is probably that of greatest significance.

In order to show how the "critical" norm for the pulse/respiratory ratio was determined it will be necessary to consider first the results obtained in the study of the 101 control cases. These comprised 101 veterans belonging to an essentially similar age group as our cardiac cases, but suffering from no detectable cardiac or respiratory disease. These cases were all put through the same exercise routine described above and the same pulse and respiratory readings were taken. Of these 101 cases, 74 showed no tachypnea after the prescribed exercise. On the other hand 27 control cases did show tachypnea (a post-exercise respiratory rate of 24 or more). Since cardiac and respiratory disease were presumably ruled out in these cases, it is necessary to explain this tachypnea on the basis of so-called "nervous" or "emotional" factors. Apparently by far the commonest evident etiological factor was the presence of physical disabilities that were obviously inducive of pain when the prescribed exercise was performed. Such disabilities varied from common conditions such as painful flat or weak feet, herniae, sacro-iliac disease, various grades of arthritis particularly of the lower extremities, to comparatively rare disabilities such as thromboangiitis obliterans. All but some five of these control cases showing tachypnea presented lesions that would be patently pain provoking under the prescribed exercise. Only these few then need be explained on "nervous factors." The writer is so impressed by the frequency of tachypnea in painful conditions, that he believes the presence or absence of an increased respiratory rate may be taken as a fairly reliable objective index of the presence of pain in cases where malingering may be suspected.

To return to our main thesis, however, we found that the average post-exercise pulse-respiratory ratio after exercise for the 74 control cases that did not exhibit tachypnea was 6.5 while for the 27 control cases that did show tachypnea it was 4.36. Accordingly, the writer feels that in our cardiac group (which has approximately the same age distribution), where no obvious respiratory, or painful somatic, or "nervous" (such as hyperthyroidism) etiological factors are present, it is permissible to assume that a

KEY TO TABLE

- 1 Reduced pulse lability is indicated by star (*) after P/R ratio
- 2 Paradoxical P/R ratio is indicated by resting being listed before post-exercise P/R ratio
- 3 Definitely pathological laboratory findings are italicized. Thus each italicized item represents a "unit" of laboratory pathology
- 4 The pathologico-anatomical diagnosis in each case may be ascertained by referring to the key letters listed in table 1

pulse/respiratory ratio of similar reduced magnitude (i.e. 4.5 or less), is indicative of impaired cardiac function

We shall now see how our laboratory studies checked up our clinical impressions. In this connection it is pertinent to emphasize that all the roentgen-ray and electrocardiographic readings were made by another physician-specialist (Dr R. S. E. Murray) who had no clinical contact with the patients, and so could not conceivably be influenced in interpreting the significance of doubtful or borderline plates or graphs. Before proceeding further we wish to mention all those laboratory findings which were considered definitely pathological. Roentgen-ray findings were considered definitely pathological only when the transverse diameter of the heart equalled or exceeded one-half the trans-thoracic diameter—except that three cases whose cardiac-thoracic ratio did not quite reach $\frac{1}{2}$ (cases Ra and m 27, M 24, and Rm 34) were also considered definitely pathological because the roentgenogram revealed specific characteristic changes in the cardiac outline. The electrocardiographic findings which were considered as definitely pathological were classified under the following five headings: (1) P-wave changes—where the P-wave exceeded 0.10 second in duration, (2) P-R changes—where the P-R interval exceeded 0.20 second in duration, (3) QRS changes—where the *base* of the R-wave exceeded 0.08 second in duration, (4) T-wave changes—including negativity of the T-wave in one or more significant leads (not including an isolated T_s), as well as characteristic alterations in the T-wave configuration, such as coving, (5) definite axis deviations (marked ventricular preponderances), evidences of markedly increased or decreased voltage (only when extracardiac interfering factors were eliminated).

A perusal of the appended tables 2-A and 2-B, in which the definitely pathological laboratory findings are italicized, will clarify the above criteria. In order to arrive at a quantitative estimate of the sum of laboratory evidences of disease it was decided to count each group of significant findings, as arranged under the headings outlined in the preceding paragraph, as constituting a unit of laboratory evidence of disease. So that, the maximal index of laboratory evidence for any individual case would be six units (one roentgen-ray and five electrocardiographic units all indicating definite pathological readings). The unit score for each case we may term the "laboratory pathology factor" (L.P.F.) for that case, thus, case A-12 which shows the following definitely pathological laboratory findings: P equals 0.12 second, PR equals 0.24 second, QRS equals 0.12 second, coronary type T-waves, poor electromotive force has an L.P.F. of 5, while Case Ra and m 22 which has a cardio-thoracic ratio of 0.5 and a marked right ventricular preponderance as the only definitely pathological laboratory findings has an L.P.F. of 2.

Key to Table Same as for table 2A

Table 3 summarizes the scores which were arrived at in the indicated manner for the various clinical functional groups of cases. It shows that the group of organic cardiac cases as a whole showed an average L P F of 1.25. The group presenting an exercise tachypnea of 24 plus had an average

TABLE III
Complete Data Organic Cardiac Cases

Clinical Grouping	Total Number of Cases	Total Number of Laboratory Pathology Findings ("Unit")	Average Laboratory Pathology "Factor"	Number and Percentage of Cases with No Definite Pathological Laboratory Findings
With tachypnea (24 plus/ per minute) after exercise	27	40	40/27—1.48	6—22*%
Without tachypnea	29	30	30/29—1.03	12—41.4%
With "paradoxical" P/R ratio	15	21	21/15—1.4	3—20%
Without paradoxical P/R ratio	41	49	49/41—1.2	15—36.6%
With reduced pulse lability (P/R less than 4.5)	10	23	23/10—2.3	1—10%
Without reduced pulse lability (P/R greater than 4.5)	46	47	47/46—1.02	17—37-%
Total organic cases	56	70	70/56—1.25	18—32*%

L P F of 1.48, as compared with an average L P F of 1.03 for the group not showing tachypnea after exercise. In other words the group with tachypnea, on the average showed 44 per cent more definite laboratory evidence of disease than the group without tachypnea. Similarly, the group with a paradoxical pulse-respiratory ratio showed on the average, 16 $\frac{2}{3}$ per cent more definite laboratory evidence of disease than the group without a paradoxical pulse-respiratory ratio. Finally the group with a pathologically diminished pulse lability (pulse-respiratory ratio less than 4.5) showed on the average 125 per cent more laboratory evidence of disease than the corresponding group without a diminished pulse lability (pulse-respiratory ratio greater than 4.5).

The last column of table 3 indicates the reliability of using these clinical groupings in predicting the absence of laboratory findings of definite pathological significance. Thus the group without tachypnea showed an incidence of cases without pathologically significant laboratory findings that was 87 per cent greater than occurred in the group with tachypnea. Similarly the group without paradoxical pulse-respiratory ratio showed an incidence of "laboratory negative" cases 83 per cent higher than was found in the group exhibiting a paradoxical pulse-respiratory ratio. Finally in the group with-

out diminished pulse lability the incidence of "laboratory negative" cases was 270 per cent higher than in the group showing diminished pulse lability

Table 5 suggests another interesting clinical hint, which however would require statistical confirmation from a much larger series of cases, before it could be considered firmly grounded. In this graphic table, the average post-exercise pulse rates for organic cardiac cases with similar degrees of severity of laboratory pathology are plotted. The dotted line indicates these averages in the cases manifesting tachypnea of 24 plus, and the dash line indicates these averages in the cases manifesting no tachypnea. The graph suggests that in cases with tachypnea, a relatively slow pulse rate is more indicative of a severe lesion, while in the cases without tachypnea the reverse holds true,—viz, a relatively fast pulse rate is more indicative of a severe lesion. One is tempted to surmise that the reason for this is that with the more severe grades of functional cardiac impairment there generally co-exists a relative prolongation of the systolic phase of the cardiac cycle, so that the organism can more readily respond to the increased oxygenation demands of exercise by a relative greater utilization of the respiratory adjustment. However, insufficient data were at hand to adequately test this supposition.

TABLE IV

Comparison Roentgen-Ray Findings with Clinical Findings (Tachypnea) as to Sensitivity

Cases Showing	Number of Cases	Number of EKG—L P "Units"	Average L P Factor for EKG Findings—Alone	Number and Percentage of Cases with Negative EKG
1 Roentgen ray evidence of disease	12	13	1.08 plus	5—41 plus %
2 Tachypnea, 24 plus	27	35	1.3—	8—29.6 plus %
3 No tachypnea	29	23	.79 plus	15—51.6 plus %
4 Total organic cases	56	58	1.04—	23—41 plus %

Table 4 shows the relatively greater sensitivity of the simplest of these clinical criteria, viz, tachypnea, as compared with the commonly used laboratory criterion of pathological roentgen-ray findings. The electrocardiographic findings as expressed in laboratory factor averages are charted against these criteria. It seems clear that the presence of pathological roentgen-ray findings per se is no better indication of the presence of pathological EKG's than the diagnosis of organic heart disease per se. (Compare items (1) and (4) in the table.) On the other hand, the presence of tachypnea (after exercise) per se, affords a 20 per cent higher correlation with positive electrocardiographic findings, and a 25 per cent lower correlation with entirely negative electrocardiographic findings. (Compare items (1) and (2).)

TABLE V

Graph Indicating the Average Post-Exercise Pulse Rates for Groups of Cases with Identical Laboratory Pathology Factors (LPF)

SUMMARY

1 No entirely satisfactory clinical method has been available for the estimation of the degree of impairment of cardiac function in ambulatory organic cardiac cases

2 Laboratory findings per se (roentgen-ray and electrocardiographic data) afford certain reliable *objective* criteria for the estimation of impairment of cardiac function in such cases

3 This study of some 200 odd cardiac cases and 100 odd controls aims to determine the correlation existing between certain readily observable objective clinical data and the corresponding laboratory data. The tabular studies rather confirm the impression that a relatively high incidence of laboratory findings indicating functional impairment is found in those organic cardiac cases showing the following clinical signs

- (a) Tachypnea after exercise,
- (b) "Paradoxical pulse/respiratory ratio" after exercise,
- (c) "Diminished pulse lability" in response to exercise

The definition of these terms is made clear in the text

4 These studies were made on a clinical group of cases (mainly World War veterans) falling predominantly into certain age groups. Similar studies should be made on other more diverse age groups, before the conclusions arrived at can be considered generally firmly grounded.

5 The most tangible deduction from this study may be expressed in the following clinical aphorism. In an organic cardiac case manifesting tachypnea after exercise, a relatively slow pulse rate after exercise is more indicative of a severe lesion than a relatively fast one.

In closing it is pertinent to reemphasize that these deductions and conclusions are considered to apply only to ambulatory organic cardiac cases, free of the influence of any drug therapy. Also that all the figures quoted represent averages, and so represent the usual tendency but not the invariable pattern of reaction of certain clinical groups of cardiac cases. In other words the clinical symptoms discussed, when present, may be considered as symptom-complexes suggestive of, but by no means pathognomonic of, the presence of impaired cardiac function. And conversely, the absence of these clinical symptoms may be considered as suggestive evidence, but again by no means conclusive evidence, of the absence of a significant impairment of cardiac function.

The author wishes to express his indebtedness to Dr Reginald S. E. Murray of the Veterans' Facility, Lyons, N. J., as without his cooperation in furnishing extremely accurate and painstaking roentgen-ray and electrocardiographic reports, this study would have been impossible.

BLOOD VELOCITY RATE AND VENOUS PRESSURE IN THE PROGNOSIS OF HEART DISEASE¹

By SAMUEL CANDEL, M D , and MEYER A RABINOWITZ, M D ,
Brooklyn, New York

THE heart is well adapted to study because of its anatomical position and the numerous expressions of its activity. It may be easily observed as to size, shape, the state of its valves and the character of muscular contraction. Its situation in the thoracic cage, surrounded as it is by air-containing viscera, makes radiographic examination possible. By expelling its contents into a closed vascular system, it builds up the arterial, capillary and venous blood pressures and succeeds in imparting motion to a column of blood, i e , velocity. The intermittent character of its contractions makes itself evident in a pulse wave and causes the propagation of minute electrical currents which may be registered graphically and interpreted. The accurate measurement of the various expressions of the physiologic activity of the heart enables us to assemble valuable information as to the state of the cardiovascular system.

Much has been written on blood velocity rate and venous pressure in heart disease. Most of the work has consisted of observations on patients during one short phase in their lives. It was therefore most natural that an attempt should be made to ascertain what changes took place in the hemodynamics of the circulatory system, when the disease process had an opportunity to regress or progress over a longer period of time. It was of particular interest to determine whether or not our studies could be of aid in prognosis.

Fifty-one cases of heart disease, rheumatic, arteriosclerotic and hypertensive, who were in-patients at the Jewish Hospital of Brooklyn, were studied. Forty-eight cases were traced one year later. Two were entirely lost. One was excluded because of the malignant nature of the disease. Of the 48, 17 were personally observed at the end of the test period. The remainder were followed through other institutions or through their family physicians.

The velocity rate (circulation time) was determined according to the method of Fishberg, Hitzig and King¹. Saccharin was injected intravenously in the antecubital fossa and the time which elapsed between the injection and the patient's experiencing a sweet taste was measured. The normal rate ranges from 9 to 16 seconds.

Venous pressure was measured by the direct method of Taylor, Thomas and Schleiter who employed an 'L'-shaped tube which was connected with a needle placed in a vein under standard conditions². The normal values are from 4 to 8 centimeters of blood.

* Received for publication October 8, 1936

From the Medical Service of Dr M A Rabinowitz, Jewish Hospital of Brooklyn, New York

C T—Circulation time in seconds

V P—Venous pressure

(V P)₂—Venous pressure after pressure over right upper quadrant

* Patient living, traced through family physician or hospital

(a) not included in statistical survey because of malignant nature of the disease

(b), (c), (d), (e), (g), Velocity rate at first observation 30 seconds At the end of one year functional capacity Class 3 Patient No 50

died 20 months after first observation Patient No 21 died immediately post-thyroidectomy

(f) Velocity rate at first observation 30 seconds At the end of one year functional capacity Class 2a

In arranging the tables which follow, in those cases on which more than one observation was made, the slowest velocity rate and the greatest venous pressure (not necessarily the coincidental one) were chosen. This was done because it was felt that these figures represented the greatest inefficiency which was registered by the particular circulatory system under study.

TABLE II

Circulation Time	Number of Cases	Number of Deaths in One Year	Mortality %
9-16 seconds	13	0	0
17-29 seconds	21	4	19%
30 seconds or more	14	8	57%

Case 50 is included in the preceding table, but it is not noted as a death. A total ablation of the thyroid gland was done 10 months after a circulation time of 42 seconds was recorded. The patient lived for another 10 months. Case 21 is also included in the above tables and is not listed as a death because death followed immediately after thyroidectomy. The operative procedure was done one year after the patient was first observed and was decided upon only after his decompensation failed to respond to any form of therapy. Cases 6 and 46 were excluded entirely. The first was one of subacute bacterial endocarditis, the second patient was semicomatose and the circulation time could not be obtained.

Berinskaya and Meerzon concluded that a marked slowing of the blood velocity had a bad prognostic significance.³ Fishberg, Hitzig and King presented a study of 59 cases of recent myocardial infarction in the *Archives of Internal Medicine* of December 1934.⁴ In 38 of these the circulation time was recorded. The following is adapted from table 3 of their article.

TABLE III

Circulation Time	Number of Cases	Number of Deaths	Mortality %
9-16½ seconds	9	1	11%
17-29½ seconds	15	2	13%
30	14	9	64%

(Adapted from Table 3 of article by Fishberg, Hitzig, and King⁴)

In both tables 2 and 3, it is evident that the mortality rate increases rapidly when the circulation time exceeds 30 seconds. The cases of Fishberg et al. were all of recent myocardial infarction and apparently were not followed up after the original investigation. It is probable that with a 12 month follow-up their markedly delayed velocity group would have presented much higher mortality rates.

In our mixed series, at the end of one year, there were six patients whose velocity rates exceeded 30 seconds and who were still alive. The importance of the finding of a very slow velocity rate is emphasized by the fact that of these six patients, five belonged to Class 3 and became decompensated on the slightest exertion. The sixth showed a remarkable improvement. At the end of the year his circulation time fell from 30 to 13 seconds. The following are synopses of the histories of these cases.

CASE REPORTS

(No 22) R F, male, aged 45 years. Chronic rheumatic valvular heart disease, mitral regurgitation and stenosis, auricular fibrillation, congestive heart failure. On admission, there were dyspnea, cyanosis, râles at both bases, fluid in the pleural and abdominal cavities and a liver enlarged to the iliac crest. The circulation time was 55 seconds. The venous pressure was 17 centimeters, and it rose to 23 centimeters after right upper quadrant pressure. Since then, he has had repeated episodes of decompensation and is incapable of even the slightest exertion. Class 3.

(No 43) I L, female, aged 45 years. Hypertension, arteriosclerosis, cardiac hypertrophy and dilatation, decompensation. On examination, the patient was dyspneic, cyanotic and had sacral and pretibial edema. The heart was enlarged both to the right and left. There was an apical systolic murmur. The liver was enlarged to 8 centimeters' breadth below the costal edge. There was ascites. The eye-grounds showed arteriosclerotic blood vessel changes. The blood pressure was 230 mm of mercury systolic and 124 diastolic. The circulation time was 38 seconds, the venous pressure was 21 centimeters. The patient decompensates very quickly* and with little exertion. Class 3.

(No 50) H B, male, aged 53 years. Hypertension, generalized arteriosclerosis, coronary sclerosis, myofibrosis cordis, auricular flutter, congestive failure with enlarged liver, pulmonary stasis and peripheral edema. The blood pressure was 240 systolic and 120 diastolic. The circulation time was 42 seconds. The venous pressure was greater than 30 centimeters. The patient was readmitted twice within a period of nine months. The last circulation time was 27 seconds. On the third admission (10 months after the first observation) an ablation of the thyroid gland was done. It was most interesting to observe that, immediately following thyroidectomy, the heart rate changed from an auricular flutter to a regular sinus rhythm. Upon discharge the patient was still slightly decompensated. The circulation time was 27 seconds. The venous pressure was 19 centimeters. He was then admitted to an institution for chronic diseases. There he had several attacks of precordial pain and pulmonary edema. He made a sudden exitus 20 months after the first circulation time of 42 seconds was recorded. Class 3.

(No 35) E C, female, aged 55 years. Generalized arteriosclerosis, coronary sclerosis, myofibrosis cordis, anginal syndrome of nine years' duration, congestive heart failure with râles at both bases, a liver enlarged to 8 centimeters' breadth below the costal edge, and ankle edema. On admission the circulation time was 31 seconds. The venous pressure was 25 centimeters. Her family physician reported one year later that she was confined to bed for more than two-thirds of the time and that she decompensated with mild exertion. Class 3.

(No 21) P W, male, aged 44 years. Chronic rheumatic heart disease, mitral regurgitation and stenosis, aortic regurgitation and stenosis, auricular fibrillation, decompensated. On examination, there were orthopnea, cyanosis, fine crepitant râles at both bases and also large sonorous râles throughout the chest. The heart was enlarged to the right and left and the liver edge was felt at the level of the umbilicus.

On two separate occasions the circulation time was 37 seconds and 45 seconds. The venous pressure was 17 centimeters. After a month, he was discharged as improved. He was followed in the out-patient department where he always showed some evidence of decompensation. Eleven months after his first admission he returned to the hospital markedly decompensated. The circulation time was 50 seconds. There was a slight improvement after therapy and then a remission. A total ablation of the thyroid gland was decided upon. Unfortunately, the patient succumbed to the procedure. Class 3.

(No 45) S W, female, aged 48 years. Hypertension, generalized arteriosclerosis, coronary sclerosis, auricular fibrillation, anginal syndrome, congestive failure with enlarged liver. The circulation time was 30 seconds. The venous pressure was 9.5 centimeters and it rose to 12 centimeters after pressure was made over the liver area. In the year that followed she enjoyed fairly good health except for occasional precordial distress. When we observed this patient a year later there was no dyspnea or cyanosis. The lungs were clear. The apex beat was in the sixth interspace two inches outside the mid-clavicular line. She was fibrillating. Blood pressure was 190 systolic and 120 diastolic. The circulation time was 13 seconds. The venous pressure was 6 centimeters and rose to 13 centimeters after making abdominal pressure. Class 2A.

TABLE IV

Venous Pressure	Number of Cases	Number of Deaths in One Year	Mortality %
0- 8 centimeters	16	3	18.7%
9-19 centimeters	26	8	30.7%
20 centimeters or more	6	1	16.6%

It is evident that there is not the same progressive correlation between increasing mortality rate and increasing venous pressure that there is between mortality rate and increasing circulation time.

We were able to recall 17 patients at the end of one year. A complete physical examination and a determination of the circulation time and the venous pressure were done. The results are tabulated in columns 6, 7, 8, of table 1. Cases 2, 9, 47, 21, 45, and 50 were of unusual interest. The last three have already been discussed.

CASE REPORTS

(No 2) D S, female, aged 21 years. Acute exacerbation rheumatic fever, mitral regurgitation and stenosis, pericardial effusion. She suffered her first attack of rheumatic fever 14 years before her present admission. On examination she showed marked pallor, dyspnea, slight cyanosis and fever. There was dullness at both bases. The heart outline by percussion showed enlargement both to the right and left. The heart tones were muffled. There were presystolic and systolic apical murmurs and a pericardial friction rub. There was no peripheral edema and no enlargement of the liver or spleen. The circulation time was 10 seconds. The venous pressure was 10.5 centimeters. She made good progress and was discharged much improved.

One year later, she returned for an examination. She reported that she felt well on ordinary effort, but that she was no longer able to indulge in tennis or swimming without dyspnea whereas before her last illness she had experienced no difficulty in

these sports. Our physical examination showed no evidence of congestive failure. The heart was slightly enlarged to the left. There was an apical systolic murmur and an accentuated pulmonic second sound. Her circulation time was now 18 seconds, a marked increase over that of the preceding year. The venous pressure was 5 centimeters.

(No 47) E. D., female, aged 44 years. Essential hypertension, nephrosclerosis, congestive heart failure. Her chief complaint was repeated attacks of whistling in the chest with shortness of breath. She appeared chronically ill. There were many musical wheezing râles, with the prolonged expiration, throughout the chest. There was an accentuated aortic second sound. The liver edge was palpable. There was no peripheral edema. She was tested in another clinic and found to be sensitive to feathers. There was much discussion as to whether the asthmatic attacks were allergic or due to heart failure. The circulation time was 14 seconds. The venous pressure was 8 centimeters. This, certainly, did not point toward the heart as being the seat of disease and responsible for the symptoms. In relation to this, we must call attention to the report of Winternitz on two cases of so-called "cardiac asthma" where the circulation time was normal.¹⁰

One year later she reported that after leaving the hospital she had been ill in bed for two months. She now showed a blood pressure of 220 systolic and 140 diastolic and a pulse rate of 96. The heart was enlarged to the right and left. There was an apical systolic murmur and an accentuated second aortic sound. There were no râles in the chest. The liver was palpated 4 centimeters below the costal edge. There was marked ankle edema. The circulation time was 30 seconds. The venous pressure was 21 centimeters and after right upper abdominal pressure it rose to 28 centimeters. There was no question now that there was myocardial insufficiency both from the physical examination and the determinations of the velocity rate of the blood and of the venous pressure.

(No 9) S. L., male, aged 19 years. Acute exacerbation of rheumatic fever, pancarditis, pericardial effusion, rheumatic pneumonitis, mitral and aortic regurgitation and stenosis. On admission he showed dyspnea and cyanosis. There was dullness at both bases and evidence of a pericardial effusion. The liver was slightly enlarged. There was no peripheral edema. The problem which presented itself was whether or not this patient was suffering from myocardial failure with decompensation or whether the underlying process was purely a severe rheumatic infection. It was the prevailing opinion that we were dealing with an acute exacerbation of an old rheumatic heart disease. This was borne out by the therapeutic test when the patient failed to respond to digitalization and diuretics. Fever continued for weeks and subsided with the return of the physical findings to a more normal state. The circulation time varied from 14 to 16 seconds. The venous pressure averaged 7.5 to 11.0 cm. He showed marked improvement.

One year later he returned saying that he had been well and had been working as a salesman with no distress. Our findings at this time were that he had no dyspnea or cyanosis and no peripheral edema. There were no râles in the chest. The apex beat was found in the sixth interspace one inch outside of the mid-clavicular line. The circulation time was 17.5 seconds. The venous pressure was 5.5 centimeters.

DISCUSSION

There appear in the literature two main theories as to the mechanism of heart failure. The first and oldest is the "back-pressure" hypothesis which stressed the concept that failure of any chamber resulted in a damming up of blood behind that chamber.⁵ Thus, dyspnea on effort and pulmonary

edema were ascribed to failure of the left ventricle which resulted in pulmonary congestion. Cardiac insufficiency associated with passive congestion of the liver and peripheral edema was attributed to failure of the right ventricle. The second and later assumption placed emphasis on diminished cardiac output as the principal factor.⁶ Proponents of this belief explained pulmonary edema as being due to a failure of the right ventricle while the responsibility for increased venous pressure with peripheral edema fell upon a failing left ventricle which was incompetent in propelling sufficient blood.

In his treatise on the failure of the circulation, Harrison says, "the theory of diminished cardiac output must be discarded, for this hypothesis fails to account for the symptoms, and measurements of the cardiac output have shown that heart failure may be associated with a normal output of the heart and that clinical improvement may be accompanied by a change in either direction or by no change of this function. The back pressure theory on the other hand offers an acceptable explanation of dyspnea and edema formation, is compatible with the clinical and pathological findings, and is in accord with the 'law of the heart' and other fundamental physiological principles."⁷

The French school of medicine has been noted for adherence to the back pressure theory and for insistence on the distinction between left heart and right heart failure. To Coisvart, Beau and Potain, the only picture of heart failure was that which we know of as right heart insufficiency. Fraentzel, Meiklen, Vaquez, Frank and Lian recognized failure of the left ventricle as a distinct entity.⁸

Left ventricular failure is brought about by hypertension, aortic valvular disease and myocardial infarction involving particularly the left ventricle. The most prominent symptoms are dyspnea and substernal oppression on exertion, paroxysmal dyspnea and acute pulmonary edema. The underlying pathology is venous stasis affecting the pulmonary circuit.⁸

Pure right heart failure with congestion of the liver and peripheral edema is most commonly seen in association with chronic pulmonary disease, congenital heart affections, tricuspid lesions and lesions affecting the pulmonary artery.

Right heart failure may be engrafted upon a chronic failing left heart. Thus, right and left heart failure may and frequently do, coexist.

Mitral stenosis is peculiar in that it places a mechanical obstruction in the out-flow tract of the lesser circulation. Pulmonary congestion, therefore, in this instance, is not predicated upon the basis of left heart failure.

There is an interesting syndrome of heart failure first described by Bernheim at Nancy in 1910.⁹ He observed a group of cases of congestive heart failure with (a) enlargement of the liver, (b) peripheral edema, (c) absence of râles in the lungs, (d) enlargement of the left ventricle. At autopsy he noted that the hypertrophy of the left ventricle was associated with a marked hypertrophy of the interventricular septum which encroached

upon the lumen of the right ventricle so that there existed virtually a functional stenosis of that chamber. The symptomatology and the physical findings can be explained only by back pressure due to stasis behind the right ventricle. It is possible, therefore, for right heart failure to precede left heart failure even though the underlying disease process is in the left ventricle.

Congestive heart failure with hepatomegaly and peripheral edema is always accompanied by an increase in venous pressure. We may therefore utilize the measurement of venous pressure as a criterion of the degree of right heart failure. A necessary corollary, therefore, is that the absence of increased venous pressure rules out right heart failure.

In cardiac failure there is a slowing of the speed of blood flow (velocity). Thus, if the circulation time (rate of blood flow) is measured and found to be slower than normal, and if, at the same time, the venous pressure is measured and found to be within normal limits, it may be concluded with reason that there exists an inefficiency of the left ventricle. There is, then, in the simultaneous determination of the circulation time and venous pressure, a method of distinguishing right from left heart failure.

We have found that there is no necessary parallel between the venous pressure (criterion of congestive heart failure) and the slowing of the blood velocity. In table 1, patients 12, 14, 35 and 39 show that in the same patient at different times in his clinical course, the rate of blood flow and the venous pressure varied markedly without showing any direct relationship to each other. In other patients we have observed very slow velocity rates with absolutely no sign of congestive failure as in patients 17, 29, and 41. Fishberg et al have demonstrated that there may be a normal or subnormal venous pressure in isolated failure of the left ventricle although there is a marked slowing of the circulation time.

It is obvious then, since the mortality rate varies directly with the circulation time and not with the venous pressure (venous pressure = index of right heart failure), that the mortality rate is dependent upon the efficiency of the left ventricle. Hence, left ventricular failure is of graver import than right ventricular failure.

Increased venous pressure can be detected without difficulty by simple physical examination. However, the circulation time can be determined only by some special procedure of which, fortunately, there are several simple ones.^{1, 11}

Since the mortality rate varies rather regularly with the blood velocity, it is clearly evident in the determination of the circulation time, there exists a real adjunct in the prognosis of heart disease.

The determination of the blood velocity has also been found useful

- (1) In differentiating dyspnea due to myocardial failure from that of bronchial asthma, cerebral and pulmonary dyspnea.¹⁰
- (2) In determining whether or not an anginal syndrome is associated with the presence of myocardial damage.¹⁰

- (3) In separating ascites and edema of cardiac from that of extra-cardiac origin¹⁰
- (4) In uncovering a masked hyperthyroidism in the face of heart failure^{10, 11, 12}

In passing we must mention that Fishberg and his co-workers have practised making pressure on the liver while obtaining the venous pressure. This was done routinely in all of our cases. We too, have found that making pressure over the right upper quadrant of the abdomen while the manometer is in the antecubital vein is of aid in determining whether or not a hepatomegaly is due to venous engorgement. In 19 cases, where there was no congestive heart failure, the average rise in venous pressure on squeezing the liver area was 0.5 centimeters. In 23 cases, where congestive heart failure with an enlarged liver was present, the average rise was 5.6 centimeters, and varied from 2 to more than 14 centimeters.

CONCLUSION

In a series of 51 cases of rheumatic, arteriosclerotic and hypertensive heart disease, 48 of which were traced for at least one year, we have found that

- 1 The circulation time is of greater significance in prognosis than the venous pressure

- 2 The mortality rate increases as the velocity of the blood flow decreases and that when the circulation time is 30 seconds or more, the mortality rate is 57 per cent for one year

- 3 Of the six patients with a circulation time greater than 30 seconds and alive at the end of a year, five were in Class 3 and decompensated with the slightest effort. The sixth patient improved clinically and the velocity rate fell from 30 to 13 seconds

- 4 Failure of the left ventricle is of graver import than failure of the right ventricle

THE COMPLICATIONS AND HAZARDS OF FEVER THERAPY ANALYSIS OF 1000 CONSECUTIVE FEVER TREATMENTS WITH THE KET- TERING HYPERTHERM *

By ROBERT M. STECHER, M.D., and WALTER M. SOLOMON, M.D.,
Cleveland, Ohio

THE beneficial effect of intercurrent infection upon patients with chronic disease was noted many years ago and naturally suggested the therapeutic value of elevated body temperatures. The feasibility of such a form of non-specific treatment was tested with tuberculin shortly after its introduction about 50 years ago. This was the first of a long series of suggestions for therapeutic fever production which have included the utilization of febrile diseases, protein fevers and numerous mechanical and electrical devices. Despite the large number of methods which have been recommended and are available, the end is not yet in sight, and scarcely a month passes without the proposal of a new device or a further refinement of an old method. This interest and activity is encouraging, for all of the available methods seem to have disadvantages, and the completely ideal procedure for therapeutic fever production still remains to be developed.

From the standpoint of therapeutic results the least common denominator of all methods seems to be the type of fever which is produced. Sweeping aside all arguments as to technic, the method of choice depends upon the ease and certainty with which a desired level of fever can be reached and maintained, the expense involved, the familiarity of the operator with the method, and, most important of all, the safety and comfort of the patient.

Because certain complications and hazards encountered in fever therapy depend entirely upon the height and duration of fever regardless of the method of production, we feel justified in presenting our observations of 1000 consecutive fever treatments given with the Kettering Hypertherm at City Hospital, Cleveland, Ohio from March 1934 to January 1936. The therapeutic results will not be discussed at this time.

The influence of higher fevers and longer treatments in increasing the hazards to the patient can be demonstrated because the treatments comprising this series fall into two distinct groups. The largest group consists of 830 treatments, during which fever of 103° F to 105° F was maintained for periods of 3 to 5 hours. These treatments were given to patients with acute and chronic arthritis, syphilis and various other diseases. The second group consists of 170 treatments, during which fevers of 106° F to 107° F were maintained for periods of 4 to 7 hours in patients with gonorrhea and its

From the Department of Medicine, Western Reserve University Medical School at City Hospital, Cleveland, Ohio

complications For the sake of convenience, fevers of 103°F to 105°F will be referred to as mild treatments, and fevers of 106°F to 107°F will be referred to as severe treatments throughout the remainder of this paper

No attempt is made to compare the complications and hazards observed in this series with those reported by other workers We believe that most of the phenomena described here may be seen in any series of induced fevers of comparable elevations and duration except those, such as skin burns, which occur only when external heat is applied to the patient Complications such as severe debility due to an induced disease like malaria, or the increasing difficulty in producing successive fevers, as in protein therapy, are lacking in this series

Some comprehension of the method used is necessary for an understanding of the problems encountered in this series The apparatus consists of a cabinet large enough to accommodate comfortably the body of a man in a prone position with his head outside The cabinet is provided with a large sliding door on each side to allow for the taking of rectal temperatures, the periodic examination of the patient's skin and the arranging of blankets as necessary Fever is produced by passing heated and humidified air over the patient's body A separate compartment at the foot of the cabinet contains an electrical resistance coil heating element which heats the air, and a blower which causes it to circulate through the cabinet A second heating element produces humidity by boiling water Automatic controls maintain air temperature and humidity at the desired levels

The patient arrives at the treatment room about 8 o'clock in the morning after a light breakfast or in a fasting state After recording the temperature, pulse, blood pressure and weight, the patient is placed in the cabinet and all covering is removed The air temperature of the cabinet, which is about 125°F at the start of the treatment, is raised as rapidly as possible to 150°F or 160°F and the humidity is kept between 30 and 40 per cent This preliminary period, during which the patient's temperature becomes elevated to the desired level, varies from one-half to two hours, but this time is not included in recording the duration of the treatment When the desired degree of fever is attained, the body is covered with a light blanket, an electric fan is directed on the face, iced water or 0.6 per cent saline is given as desired and ice is rubbed on the face At this time the temperature and humidity of the air in the cabinet are adjusted to the lowest level at which the desired body temperature can be maintained When the treatment is finished the patient is removed from the cabinet, and the temperature falls in an hour or so to the pre-treatment level After a bath the patient is sent to the ward or allowed to go home

This study deals with 1000 consecutive fever treatments divided as mentioned above, into 830 mild treatments and 170 severe treatments The mild treatments were given to 142 patients of whom 62 had chronic arthritis, 21 had acute arthritis, 9 had rheumatic fever or chorea, 15 had syphilis and

35 had a variety of conditions. The patients with chronic arthritis had treatments at 103° F. to 104° F. for three to four hours, the others usually had 105° F. for five hours. The number of treatments per patient averaged 5.8, but varied from one treatment in 28 patients to 23 treatments in one patient. The severe treatments were given to 62 patients with gonorrhea, either genital or metastatic. An attempt was made to treat these patients at as near 107° F. as seemed consistent with safety, and this temperature was maintained in each treatment at least five hours, and preferably seven hours. Many of the patients in the first group who received mild treatments were debilitated, undernourished and aged beyond their years, while those in the second group who received severe treatments were young, robust and in excellent general health. Despite the marked difference in physical condition of the two groups, only 39, or 4.7 per cent, of the mild treatments had to be discontinued, compared to 24, or 14.1 per cent, of the severe treatments. Of the 39 mild treatments which were discontinued, 21 were discontinued because of insistence on the part of the patient, lack of cooperation or delirium, five because of blisters or burns, eight because of diarrhea or persistent vomiting, three because of shock and two because of tetany. Of the 24 severe treatments, 12 were discontinued because of insistence on the part of the patient, lack of cooperation or delirium, seven because of blisters or burns, two because of diarrhea or intestinal cramps and three because of shock. When these figures are arranged in parallel columns and reduced to percentages of treatments given, the difference between mild and severe treatments becomes apparent.

Our plan to weigh patients routinely before treatment and again prior to their discharge from the department was seriously disrupted because of the difficulty of getting them upon the scales. This was the case in arthritics with painful or disabling disease and in all patients with severe nausea or debility following treatment. The observed changes in weight during therapy were closely related to the amount of fluid ingested and to vomiting. We have data on 172 mild treatments. In 67 instances the weight after treatment was within one pound of the pre-treatment level. This was considered no change. In 19 instances there was a gain in weight which varied from one to six pounds, while in 86 instances there was a loss. In nine treatments the loss was less than three pounds, in 29 treatments it was three to five pounds and in 27 treatments it was five to seven pounds. In 21 treatments weight loss varied from seven to 15 pounds. Of these 21 treatments, 19 were given to three patients. Excessive weight loss occurred repeatedly in successive treatments of the same patients who took fluids poorly and vomited repeatedly. In 18 severe treatments, weight was unchanged in eight, there was a gain in five and a loss in five, never more than 6 pounds. The weight changes observed in fever treatments are temporary as restoration to pre-treatment weight takes place within 48 hours in most instances.

Nausea or vomiting is a frequent source of discomfort. Patients often

feel nauseated or vomit once or twice during the treatment but this occurs most often in the rest period following the treatment, particularly in patients who must get up and dress to go home. In rare instances, vomiting occurs with sufficient severity during the course of the treatment to necessitate its premature termination. Nausea or vomiting was observed in 28.1 per cent of the 830 mild treatments or 233 times, and in 35.5 per cent of the 170 severe treatments or 57 times. The patients who received repeated treatments were studied to determine if the incidence of nausea or vomiting increased with successive treatments and whether or not there was an individual susceptibility to nausea or vomiting. Of 114 patients who received two or more mild treatments, 45 had nausea or vomiting. These patients received 399 treatments, and nausea or vomiting occurred in 52 per cent or 207 times. Of 37 patients who received two or more severe treatments, 10 had nausea or vomiting. These patients received 67 treatments, and nausea or vomiting occurred in 55 per cent or 37 times. Thus it is seen that the vomiting patients receiving several treatments had this symptom in 52 per cent and 55 per cent of their treatments compared to 28.1 per cent and 33.5 per cent of the whole group. Some patients escape nausea entirely, even on repeated treatments, while patients with nausea receiving several treatments have a higher treatment incidence than the whole group.

It was thought that the use of morphine increased the incidence of these gastric disturbances, but the figures do not substantiate this view. In 830 mild treatments, morphine was administered 672 times or in 80.9 per cent of the treatments. Of the 399 treatments given to 45 patients who developed nausea, morphine was administered 307 times or in 77 per cent. In the 170 severe treatments, morphine was administered 145 times or in 85.3 per cent. Of the 67 severe treatments given to 10 patients who developed nausea, morphine was administered 52 times or in 74.6 per cent. When possible morphine was withheld on succeeding treatments of those patients who were nauseated or had vomited previously. Although these figures seem to indicate that morphine played little or no part in the causation of vomiting several individual patients escaped vomiting when morphine was omitted.

The effect of fever therapy in causing anorexia was observed by noting the first regular meal which the patient was able to eat after treatment. In 188 mild treatments the patient was able to eat supper on the day of treatment in 35 instances or in 18.6 per cent (no anorexia). He was able to eat breakfast the next morning in 123 instances or 65.4 per cent (anorexia for 12 to 18 hours), and he was unable to eat until the following noon in 30 instances or 16 per cent (anorexia for 18 to 24 hours). Of 56 severe treatments the patient ate his supper on the day of treatment in 20 instances or 35.7 per cent (no anorexia), breakfast next day was the first meal in 25 instances or 44.6 per cent (anorexia for 12 to 18 hours), and he was unable to eat until the following noon in 11 instances or 19.7 per cent (anorexia for 18 to 24 hours). This disparity between the two groups is remarkable, espe-

cially when one considers that the severe treatments were not terminated until later in the day, usually from three to five hours nearer supper time, than were the mild treatments. This is a further indication of the vigor and robustness of the patients treated for gonorrhea and the weakness and debility of the other group. Inasmuch as patients miss breakfast and lunch on the day of treatment prolonged anorexia is undesirable, especially in debilitated patients.

Burns which necessitate terminating fever treatments constitute but a small proportion of the burns produced. In most instances the burns are blisters of small size and heal without scar formation, although second degree burns have been seen. Patients are warned of this danger of burns and even of scars, particularly when severe treatments are contemplated, and therapy is not discontinued because of this unless it seems likely that burns will be severe. They occur only on the ventral surface of the body and are most frequently seen over bony prominences, in scars, on pendulous breasts or on those other portions of the skin which Bierman has shown to be relatively intolerant of heat. In 830 mild treatments, burns were observed in 18 instances or 2.2 per cent. In 170 severe treatments, however, burns were seen in 23 instances or 13.5 per cent. It must be remembered that these thermal injuries to the skin result from hot and humid air alone, for the fever cabinet is so constructed that the patient's skin cannot come in contact with a heating element.

Tetany was occasionally seen, but only two treatments were interrupted because of it. Many mild instances probably occurred for patients occasionally complained of muscle cramps or stiffness of the hands. This is usually seen early in the treatment as the body temperature is rising and before morphine is given. The symptoms are fleeting, usually promptly relieved by lowering the cabinet temperature temporarily, the administration of morphine or of calcium gluconate intravenously. The tetany which occurs during fever treatments is due to alkalosis caused by the hyperventilation resulting from the respiratory stimulus of hot air to the skin. No alteration in calcium metabolism occurs, and because tetany develops early in the treatment, it is probably not related to chlorine metabolism. Morphine, because of its effect in depressing respiration, seems the ideal preventative. We have not noted undue cyanosis from its use.

Herpes labialis occurred in 45 of the 142 patients given mild treatments, or 31.7 per cent, and in 19 of the 62 patients given severe treatments or 30.6 per cent. The figures are given in relation to the number of patients, rather than the number of treatments, because this complication occurs but once in an individual patient during any continuous series of treatments. On one or two occasions herpes labialis followed the second treatment only, but otherwise they were seen only after the first treatment. A second attack has been observed once in a patient whose last previous treatment was given more than three months earlier. Herpes labialis appears three to five days

after the first treatment, remains five days and heals without leaving a scar. The lesions may be very extensive, covering the lower half of the face including the external and internal nares and involving the buccal mucosa.

The rarest accident in our experience, but by far the most alarming, and the one which constitutes the greatest hazard in fever therapy, is the occurrence of sudden and uncontrolled hyperpyrexia associated with mania and followed by deep coma, circulatory collapse and other symptoms closely resembling those of shock. This condition was seen three times in each group with an incidence in the mild and severe treatments respectively of 0.36 per cent and 1.76 per cent. In the three instances occurring during mild treatments the uncontrolled temperature rise was moderate, the collapse was less profound, and recovery was more prompt than in the cases with severe treatments. The affected patients receiving mild treatments had repeated subsequent treatments without untoward results. The sequence of events as they occurred in a patient who was being treated for gonorrhea was as follows: the patient's temperature had been between 106.8°F and 107.2°F for 40 minutes when muscular twitchings were noted, his temperature rose to 107.8°F in five minutes despite the fact that both cabinet doors had been opened. He was removed from the cabinet promptly, an electric fan was directed upon his body and he was kept wet with tepid water. His temperature continued to rise, he was pulseless, his lips were pale, and he was in deep coma. His heart sounds were inaudible, and he had an involuntary bowel movement. After adrenalin was given intramuscularly, his heart sounds became audible, the heart rate was 200, but no peripheral pulse could be felt. His temperature reached 109°F . He was given 50 c.c. of 50 per cent glucose solution intravenously. A half hour later his pulse improved, the blood pressure rose to 78 over 50, the temperature fell to 107° , he recovered from his coma but was completely disoriented. After another half hour his temperature was 104° , he became oriented, and suddenly had copious projectile vomiting, severe abdominal cramps and a rigid abdomen. The vomiting and rigid abdomen persisted for about 72 hours. He was observed closely as a patient with suspected intestinal obstruction, but he made an uneventful recovery without operation. Another patient, treated for gonorrhea, started with mania followed by deep coma and circulatory collapse. He had a severe epileptiform seizure lasting about five minutes. Upon recovery he was found to have right facial paralysis and aphasia, both of which symptoms disappeared within about 10 days. It is such experiences, rare though they be, which remind us of the seriousness of fever therapy at high temperature levels.

SUMMARY

Attempts at artificial fever production for the past 50 years have resulted in the development of many successful methods based upon various principles. The complications and hazards of fever therapy depend primarily upon the height and duration of the fever produced.

The complications and hazards observed in 1000 consecutive fever treatments given with the Kettering Hypertherm have been analyzed. Two types of treatment were given: (1) mild treatments, given chiefly to patients with various chronic diseases, limited to a body temperature of 105° F, and never maintained longer than five hours; and, (2) severe treatments, given to patients with gonorrhea, in which a body temperature of 106° F to 107° F was maintained for five to seven hours. The proportionate number of treatments which had to be discontinued, the incidence of skin burns produced, the incidence and severity of circulatory collapse were much greater in the severe treatments than they were in the mild treatments. The incidence of anorexia and excessive loss of weight after mild treatments was greater than after severe treatments. The incidence of herpes was unaffected by the severity of the treatments.

Despite the complications and hazards observed, the production of artificial therapeutic fever, with body temperatures even to 107° F maintained for five hours or longer, under proper conditions of supervision has proved to be a practical and satisfactory procedure.

LIVER FUNCTION IN RHEUMATOID (CHRONIC INFECTIOUS) ARTHRITIS; PRELIMINARY REPORT*

By WILLIAM B RAWLS, M D , F A C P , SAMUEL WEISS, M D , F A C P ,
and VERA L COLLINS, M D , *New York, N Y*

DURING the past few years, much interest has been focused on the subject of decreased dextrose tolerance in acute infectious diseases. Williams and Dick¹ found a decreased tolerance in 41 per cent of patients and they also found a similar disturbance in carbohydrate metabolism in experimentally induced toxemia in animals. Their paper contains an excellent review of the literature.

Two explanations have been offered for the "diabetic" type of dextrose tolerance curves obtained in these conditions. Some authors^{1,2,3} ascribe it to lack of endogenous insulin caused by the functional impairment of the islets of Langerhans, while others^{4,5,6} maintain that it is due to an interference with the action of the available insulin, whether of endogenous or exogenous origin. These interpretations are based upon the belief that the normal dextrose tolerance curve is dependent upon an increase in the circulating insulin consequent to pancreatic stimulation from the dextrose administered. However, Soskin et al.⁷ have shown recently that a normal dextrose tolerance curve may be obtained in a completely depancreatized dog which is receiving an amount of insulin and dextrose just sufficient to maintain the blood sugar at a constant level. They also state⁸ that "an animal in this condition shows a hypoglycemic reaction at least as great as that of a normal dog following the cessation of prolonged administration of dextrose." They reason, therefore, that the normal reactions to the administration of dextrose do not require the secretion of additional insulin and that the abnormal curves observed in toxemia do not result from the lack of extra secretion.

From the results of simultaneous observations on the sugar content of the blood entering and leaving the liver during tests for dextrose tolerance, they⁷ concluded that "in the presence of a sufficiency of circulating insulin, but not necessarily of an extra secretion from the pancreas, the normal liver responds to administered dextrose by decreasing its own output of blood sugar which it previously had been supplying from its own resources." Their findings have been substantially confirmed by Tsai and Yi⁹ who calculated the quantity of sugar entering and leaving the liver by means of a flowmeter. Soskin et al.^{7,8} then concluded from their experiments that

* Received for publication September 24, 1936

From the Arthritis and Gastro-Enterological Clinics of the New York Polyclinic Medical School and Hospital

Read in abstract at the convention of the National Society for the Advancement of Gastroenterology, Atlantic City, N J, June 5, 1936

the toxemia probably interferes with the homeostatic mechanism of the liver as postulated above, through its effect on the liver itself. Sweeney and his associates^{5,6} believe that the toxemia acts, not by suppressing the endogenous insulin supply, but rather by interfering with the function of insulin, whether of endogenous or exogenous origin. Yannet and Darrow¹⁰ during the course of intoxication in rabbits produced by the intravenous injection of diphtheria toxin did not find any gross disturbance in carbohydrate oxidation. They did observe changes in the liver, however, and concluded that the observed changes in carbohydrate metabolism were due to a disturbance in hepatic function. Soskin et al¹¹ found that the intravenous injection of diphtheria toxin into normal dogs caused a definitely prolonged dextrose tolerance curve, while the injection of boiled toxin was without effect. In depancreatized dogs, the curves after the injection of toxin were even more abnormal than in normal animals, although the preliminary curves were quite normal. They concluded, therefore, that abnormal dextrose tolerance occurring in cases of toxemia was due to the effects of the toxemia on the liver and not on the pancreas. This is not surprising when one considers that, incidental to its function of detoxication, the liver bears the brunt of the toxemia which accompanies acute or chronic infection. Because of these observations, a study was begun in 1932 to determine whether any disturbed liver function occurred during the toxemia of rheumatoid (chronic infectious) arthritis.

Patients were selected on admission to the clinic and divided into severe, moderately severe and mild rheumatoid arthritis. Only those patients with classical symptoms of rheumatoid arthritis were included in this study.

The Azorubin S test was selected for the liver function test. Tada and Nakashima¹² in a study of 62 dyes found that, while other dyes were excreted in large part by the kidneys as well as by the liver, 95 per cent of intravenously injected Azorubin S was eliminated by the liver and only 5 per cent by the kidneys. Using the duodenal tube, they found that in normal persons the dye appeared in the bile in 17 minutes. Weiss¹³ concluded that this test seemed to measure the functional capacity of the liver quite as well as the Rosenthal test.

TECHNIC OF THE AZORUBIN S TEST

The duodenal tube is passed in the morning on a fasting stomach. When the tube reaches the duodenum and a yellowish-brown bile begins to flow, 4.0 c.c. of a 1.0 per cent solution of Azorubin S are injected intravenously. Five minutes after the injection of the dye, 40 c.c. of a 25 per cent magnesium sulphate solution are injected through the duodenal tube. In normal individuals a characteristic, deep red bile appears about 17 minutes after the injection of the dye.

From 15 to 30 minutes was accepted as the normal appearance time of the dye. Less than 15 minutes and more than 30 minutes indicated liver

dysfunction in proportion to the decreased or increased appearance time of the dye. The interpretation of liver dysfunction in patients with a decreased appearance time is based on the findings of Whipple, Peightal and Clark¹⁴ who reported a hypersecretion of phenoltetrachlorophthalein with small doses of phosphorus which they attributed to the irritative effect of the phosphorus on the parenchyma of the liver. Soskin and Mirsky,¹⁵ working with dogs in which liver damage had been produced by the intravenous injection of diphtheria toxin, found three different stages of dextrose tolerance depending upon the extent of liver damage. They concluded that Stage I (early liver damage) "is characterized by an early decline in the inhibitory effect exerted by the administered sugar so that the liver fails to decrease its own supply of blood sugar as rapidly as normal and a 'diabetic' type of tolerance curve results."

ANALYSIS OF 100 CASES

In four cases the appearance time was less than 10 minutes, in 32 it was 10 to 15 minutes, in 45, 15 to 30 minutes, in four, 30 to 35 minutes, in nine, 35 to 40 minutes, and in six, over 40 minutes. Of the entire number studied, 55 per cent showed some liver dysfunction. In 15 patients with osteo-arthritis, four (28 per cent) showed liver dysfunction, compared to 55 per cent with rheumatoid arthritis. However, the series of patients with osteo-arthritis is too small to permit definite conclusions. The following patients with rheumatoid arthritis showed liver dysfunction: 27 of 34 severe cases (73 per cent), 21 of 44 moderately severe cases (47.5 per cent), and seven of 22 mild cases (25.25 per cent).

From these figures it would appear that to some extent the liver dysfunction is parallel to the severity of the disease. There was no relation between the duration of the disease and the liver function. Although no control series is reported here, liver dysfunction in patients with severe rheumatoid arthritis is so much more frequent than in patients with mild rheumatoid arthritis (73 per cent compared to 25.25 per cent) that it suggests that liver dysfunction in such a high percentage is an abnormal finding. Cytological examinations of the bile in 50 cases showed abundant leukocytes in 24, or 48 per cent. Some patients with achlorhydria responded to stimulation with histamine or neutral red. Many of them showed an abnormal liver function test.

SERUM PROTEINS

A quantitative determination of serum proteins was made in patients showing liver dysfunction. In most cases, there was a slight reduction of the total serum protein and a reversal of the albumin-globulin ratio. This occurred both in cases having a rapid dye appearance time and in those having a delayed appearance time. For example in one case of rheumatoid arthritis the dye appeared in 37 minutes, the total serum proteins were 6.07

per cent, albumin, 3.5 per cent, globulin, 2.57 per cent, and the ratio, 1.36. In another case, the dye appeared in 12 minutes, the total serum proteins were 6.27 per cent, albumin, 3.81 per cent, globulin, 2.46 per cent, and the ratio, 1.55. A few cases with a normal Azorubin S test gave a reduction of the serum protein and a reversal of the albumin-globulin ratio. In the majority of cases studied, there was a correlation between liver dysfunction, the reduction of serum proteins and reversal of the albumin-globulin ratio.

TREATMENT OF LIVER DYSFUNCTION

Where the bile showed an abundance of pus cells, cocci, etc., 10 c.c. of choleval were given intravenously twice weekly. Usually six to eight injections were given, depending upon the improvement of the cytology of the bile. When choleval was omitted, decholin-sodium was given intravenously in order to increase biliary drainage but, where a number of injections was given, a 5 per cent solution was used in order to prevent excessive secretion in those patients who may have had partial obstruction. This preparation has a tendency to increase biliary secretion and thus increase the elimination of detritus from the biliary tract.

DIET

The diet was regulated according to the requirements of each patient. In some patients with liver dysfunction, a high carbohydrate diet was given, and frequently there was a gain in weight and improvement in the constitutional symptoms. As far as could be ascertained, this did not produce harmful effects. This agrees with the recent reports of Bowen and Lockie.¹⁶ A high protein diet was used in those patients showing nutritional edema. In view of the lowered values for serum proteins and the reversed albumin-globulin ratio in rheumatoid (chronic infectious) arthritis, noted previously by Davis¹⁷ and confirmed by us, it is suggested that the diet be adjusted to conform with the requirements of each individual patient.

DISCUSSION

A long series of papers has appeared on the relation of the liver function to plasma proteins. Kerr, Hurwitz and Whipple^{18, 19, 20} noted a regeneration of serum proteins following a plasmapheresis, the globulin being replaced more rapidly than the albumin. They also noted that, after a 50 per cent depletion of serum proteins, regeneration took place in five to seven days. This is the time required for regeneration of the liver cells after hepatic necrosis produced by carbon tetrachloride. Recently, Whipple and his associates^{21, 22} have given support to the theory that the liver is intimately concerned in the formation of serum proteins. The literature on the relation of hepatic disease to serum proteins has recently been reviewed by Snell.²³

It has frequently been reported that, in advanced chronic hepatic disease, there is often a moderate reduction in the total serum protein. This reduction occurs mostly in the albumin fraction with reversal of the albumin-globulin ratio. In the less advanced cases albumin may be only moderately reduced but globulin may be increased. Rowe²⁴ believed that infection is probably responsible for these findings. Snell²³ concluded that "one of the fairly constant effects of parenchymatous hepatic disease is reduction in the serum albumin and reversal of the albumin-globulin ratio, that these changes are most probably related to deficient production of protein by the liver, and that for this reason they may have some diagnostic and prognostic significance, and finally, that the serum albumin is often at or near a level which makes the production of ascites and edema relatively easy." His work is in accord with that previously reported by Myers and Keefer²⁵.

Davis¹⁷ found a definite reduction in the serum albumin, a rise in the serum globulin, and a reversal of the albumin globulin ratio in all cases of severe rheumatoid arthritis. Although a greater change occurred in those cases classed as severe rheumatoid arthritis, less severe cases also showed some change. It is interesting to compare his findings in normal cases with his reports on one case of tumor of the liver, one of acute cholecystitis, and one of pernicious anemia, all of which may have had liver involvement. The mean findings in these three cases were albumin, 4.05 per cent compared with 4.70 per cent in the normal group, globulin, 2.94 per cent compared with 2.26 per cent in the normal group, and the albumin-globulin ratio, 1.38 compared with 2.12 in the normal group. Although the degree of change was less, the findings in these three cases were similar to those observed in rheumatoid arthritis.

In view of the findings of Myers and Keefer²⁵ and Snell²³ of the reversal of the serum albumin-globulin ratio in liver disease, and of the present findings of liver dysfunction in 73 per cent of cases with severe rheumatoid arthritis, it is reasonable to assume that in most instances the changes in the serum proteins mentioned above and those also found by Davis¹⁷ in rheumatoid arthritis may have been due to liver dysfunction.

Snell²³ stated that the principal effects referable to a reduced albumin content of the blood serum of patients with hepatic disease are related to the production of edema and ascites. He believed that, although the "edema level" (4 to 5 gm per 100 cc) for the total serum proteins is not often reached, the disproportionate reduction in the serum albumin may reduce the osmotic pressure of the blood serum sufficiently to produce transudation, especially in regions where venous stasis occurs. Wells and his collaborators²⁶ have shown that, by direct measurement, the specific osmotic pressure of serum is a linear function of the concentration of albumin, the globulin content being relatively unimportant. It must be remembered, however, that there are other factors which may play a rôle in the causation of edema and ascites and that the lowered serum albumin may be only a contributing

factor The above may offer some explanation for the edema found in some cases of rheumatoid arthritis and possibly for the many varied clinical syndromes appearing in this protean disease It is also further suggestive evidence that rheumatoid arthritis is infectious in character

CONCLUSIONS

1 Liver dysfunction, as determined by the rate of excretion of Azorubin S, was present in 55 per cent of 100 patients with rheumatoid (chronic infectious) arthritis

2 Liver dysfunction occurred with greater frequency in patients with severe than in those with mild rheumatoid arthritis

A MEDICAL POET LAUREATE, ROBERT BRIDGES, M D , POET LAUREATE OF ENGLAND 1913 TO 1930¹

By COMMANDER LOUIS H. RODDIS, F A C P , *Medical Corps, United States Navy*

THE Poet Laureate of England holds an official position of peculiar dignity and honor, even though the duties are nominal and the salary somewhat remarkable—a barrel of wine and one hundred and twenty pounds a year. The title is obtained from the laurel or bay, in classical times the crown of the hero and poet, the lover being crowned with myrtle. In 1921, Professor Broadus published a study of the office of the Poet Laureate, almost the first investigation of the subject made, and there still remains for some minor poet or literary historian, the pleasant task of writing the lives of the Laureates. The list, omitting some doubtful and “volunteer” Poet Laureates, includes but sixteen names and as a matter of interest they are here given:

Ben Jonson
John Dryden
Thomas Shadwell
Nathan Tate
Nicholas Rowe
Lawrence Eusden
Colley Cibber
William Whitehead

Thomas Warton
Henry Pye
Robert Southey
William Wordsworth
Alfred, Lord Tennyson
Albert Austin
Robert Bridges
John Masefield

Only one medical man has held the title, Robert Seymour Bridges, who was born at Walmer, Kent, England, October 23, 1844. His parents were in more than easy circumstances, and he was educated at Eaton and Oxford. His college was Corpus Christi, where he graduated B A , with distinction, having still further distinguished himself as an oarsman. After a short period of travel on the continent he entered as a student at St. Bartholomew's Hospital from which he received his degree of M B , in 1874, and where he served as house physician. Having completed his service he was appointed casualty physician at “Barts,” as St. Bartholomew's has been known to generations of English physicians, and later was elected assistant physician to the Great Northern Hospital and to the Hospital for Sick Children in Grand Omond Street.

* Received for publication October 2, 1936

This is the ninth of a series of portraits of medical poets. Those which have previously appeared in the ANNALS OF INTERNAL MEDICINE are: Joseph Rodman Drake, February 1929, Oliver Wendell Holmes, June 1930, Oliver Goldsmith, May 1932, Wm. Savage Pitts, January 1933, Lieutenant Colonel John McCrae, June 1933, Dr. Richard Shuckburgh, June 1934, Johan Christoph Friedrich Schiller, March 1936.

In 1878 he published a paper in the St Bartholomew's Hospital Notes, "An Account of the Casualty Department," in which he recorded his experiences as admitting physician. From nine o'clock until twelve noon he spent interviewing patients and sending them to the appropriate clinical outpatient departments for treatment. In a year he saw 30,000 patients, two-thirds of these new cases. His whole article gives a clear and striking picture of the casualty work of this great London Hospital more than half a century ago. He also contributed a report on a case of rheumatic fever, treated by splinting the affected joints with good results. His third contribution to literature was a semi-humorous poem of 558 lines, written in Latin and describing the foundation of St Bartholomew's Hospital, with characterizations of its staff.

"Carmen Elegiacum Roberti Bridges de Nosocomii
Sancti Bartholomaei Londiniensi"

Such evidences of the classical learning of the author indicate how the medical tradition for classical scholarship established by Linacre, Caius and Heberden was carried on into the Victorian age.

Bridges had begun to write verse at an even earlier period, and his first volume of poetry appeared in 1873. From then until his death he continued to publish isolated verse, dramas, and successive volumes of poems. His last work, "The Testament of Beauty," appeared on his eighty-fifth birthday, so that his period of productive activity as a poet covered 56 years.

A number of physicians have distinguished themselves in art, literature and science, and still continued in the active practice of their profession. Medicine, however, is a jealous mistress, and many more have forsaken her to follow another love. This was the case with Bridges, and in 1882 he gave up his practice to devote himself more and more to poetry and scholarship. The possession of abundant private means enabled him to follow his inclinations in this respect without any difficulty. It is of interest to note that "Prometheus the Fire-Giver," one of the most ambitious of his earlier works, was published in 1883, the year after he had definitely abandoned Medicine.

To the end of his long life he remained a poet and scholar. Few other English poets have been such profound students of the art of versification or have admired, studied, experimented and exalted the use of English as a medium of expression. He was the author of a book on "Milton's Prosody," a penetrating study of rhythm and sound in English poetry. He was also one of the founders of the Society for Pure English and was the general editor of its publications. S P E Tract No 9 had as joint authors, Dr Bridges and Dr Cuthbert Morton. It was on the language of anatomy, so we see here his return to a medical theme. The object of the pamphlet was "to condemn the action of those who are moving to introduce a formal Latin international terminology into the British Schools of anatomy on the false note that it will be of service to international science." This was a plea

to use an English terminology His last work, "The Testament of Beauty," is an attempt to introduce a radical change in English spelling Indeed, Bridges was as distinguished in the field of English scholarship as he was as a poet This preoccupation with scholarship, and what one might call the technical feature of versification, led to many of his poems giving an impression of careful design rather than spontaneous inspiration This quality of his work is well shown in one of his most often quoted poems, "London Snows"

"When men were all asleep the snow came flying,
In large white flakes falling on the city down,
Stealthily and perpetually settling and loosely lying,
Hushing the traffic of the drowsy town,
Deadenng, muffling, stifling, its murmurs failing,
Lazily and incessantly floating down and down"

Of the two eternal themes of the poets, Love and Nature, Bridges was concerned primarily with the latter His love poems are few and justly criticized as lacking in passion and power Some of these, however, are not lacking in a deep and simple tenderness, as in this

"When death to either shall come,
I pray it be first to me,
Be happy as ever at home,
If so, as I wish, it be

Possess thy heart, my own,
And sing to the child on thy knee,
Or read to thyself alone,
The songs that I made for thee

Bridges has well carried on the tradition of English poetry as a mirror of the natural beauty of the English countryside, and has often in his verse celebrated

"Fair England in Her Pastoral Dream"

Here is a stanza worthy of Spencer

"There is a hill beside the silver Thames,
Shady with birch and brush and odorous pine,
And brilliant underfoot with thousand gems
Steeply the thickets to his floods decline"

The flowers, beloved of all the poets, are often found in his verse

"Pansy and Poppy-seed
Ripened and scattered well

And silver Lady-smock
The meads with light to fill,
Cowslip and Buttercup,
Daisy and Daffodil"

The appointment of Bridges as Poet Laureate in 1913, as the successor of Alfred Austin, was a great surprise to many. Though recognized as a poet and scholar of high rank, he was not well known to the general public who would have welcomed some more popular poet, as Kipling or Alfred Noyes. Kipling at the time was the most famous, as he was the most

ROBERT BRIDGES

national of the living English poets. None of the others had written one poem which all people knew, while he had written a dozen. It is said that he was not favored as a royal poet because of reference to Queen Victoria as the "Widow of Windsor."

The appointment, however, did not lead to as much criticism as was received by his predecessor in office. King Edward had a very poor opinion of the work of Alfred Austin, and in a letter to Lord Salisbury (quoted in

Sir Sidney Lee's Biography of Edward the Seventh) the King said, "I always thought that Mr Austin's appointment was not a good one, but as long as he gets no pay it would, I think, be best, to renew the appointment in his favor" A little later he forwarded some of Austin's poetry to Salisbury and refers to it as "trash"

During the war there were remarks on the absence of war poetry on the part of the Laureate He wrote, however, a number of war poems which were published anonymously These were collected in 1920 in a volume entitled, "October and Other Poems" The supposed silence of the Laureate during the war led a Member in the House of Commons to inquire if the Poet Laureate should not be officially requested to "earn his butt of sack"

"The Testament of Beauty," Dr Bridges' last work, was published on his 85th birthday and attracted more popular attention than any of his other poems This was partly due to his adoption of simplified spelling "There" became "ther," "captive" became "captiv," "will" became "wil" Silent letters are almost entirely dispensed with throughout the poem of 190 pages It excited a great deal of controversy as do all such innovations, the more so that it was the work of the Poet Laureate and dedicated to the King One line in it, "wher ther is any savagery, thei wil be war," was taken as an example of his simplified spelling and little was said in the press accounts and reviews of the poetical merit of the work

Dr Bridges received many honors other than that of Laureate Oxford is only one of many universities that bestowed academic distinctions upon him He was made Doctor of Laws and a Doctor of Literature The Order of Merit, one of the most prized decorations, granted only for pre-eminence in art, literature, military affairs, and statesmanship, was bestowed upon him by the Sovereign In 1920 he was elected to Fellowship in the Royal College of Physicians

He died at his home, Chiswell House, Boars Hill, Oxford, April 21, 1930 He maintained the tradition of age among Poet Laureates by living for 85 years His three predecessors were Austin, who died at 79 years, Tennyson at 81 years, and Wordsworth at 80 years, an average of 80 years

There is an interesting story told of Bridges and his successor as Laureate The doctor was fond of bicycling, and on one occasion he had a puncture in his front tire, on the slope of Boars Hill just at dusk, and was assisted in the repair of the tire by John Masefield

Bridges was a handsome man and distinguished in appearance He looked the part of a poet and a poet laureate The portrait which illustrates this article shows him seated in his garden, a fitting picture as he was a lover of gardens and flowers and celebrated them repeatedly in his verse Another well known picture of the poet shows him seated at a piano, presented to him by admirers on his eightieth birthday Like so many poets and physicians he was an excellent amateur musician

CASE REPORTS

"ABDOMINAL INTERMITTENT CLAUDICATION" AND NARROWING OF THE CELIAC AND MESENTERIC ARTERIES "

By WILLIAM B SEYMOUR, M D , and AVERILL A LIEBOW, M D ,
New Haven, Connecticut

DEPRIVATION of the blood supply to the viscera is important among the causes of abdominal pain. The effects of sudden vascular occlusion are dramatic and well known. More obscure are the symptoms and pathology of gradual occlusion. Since the literature heretofore has treated these in a very stepmotherly fashion, the correlation of available clinical and pathological data may be of value.

CASE REPORT

A spinster of 76 was admitted to the medical ward complaining chiefly of abdominal pain after eating. She had been in good health until about six months before admission. At this time she began to experience numbness in the left calf upon exertion, tingling sensations in the fingers, and constant tinnitus. The abdominal pain began three months before admission. Immediately upon the ingestion of any food except water and fruit juices there would appear a sharp steady pain in the region of the umbilicus radiating to the symphysis pubis, left lower quadrant and back. The pains would last 5 to 30 minutes and were followed by a constant slight dull ache in the epigastrium. On two occasions she had been nauseated and had vomited thin colorless material. One week before admission she had had a watery diarrhea of two days' duration. She thought that her stools had been black at times. There had been no abdominal distention. On account of the pain her diet had been entirely fluid and she had lost a considerable but indeterminate amount of weight.

Upon physical examination the weight loss was apparent in the dryness and looseness of the atrophic skin. Subcutaneous tissue was practically absent. The rectal temperature was 99.8° F, the pulse 72 and the respirations 18. There was marked evidence of arteriosclerosis: the retinal vessels were thickened and tortuous and the arteries of the extremities were firm cords. Pulsations were appreciable in the right femoral and dorsalis pedis arteries, absent in the left. In the right thigh the blood pressure was about the same as that in the right arm (200/80), but in the left thigh it could not be determined. This extremity was definitely cooler than the right. Its calf and thigh diameters were, however, the same as those of the right. The apex impulse of the heart was best palpated in the fifth intercostal space 7 cm from the mid-sternal line. The rhythm was regular and the sounds were of fair quality with accentuation of the aortic second sound. A loud harsh systolic murmur was heard at the apex and a high pitched blowing diastolic at the base, most audible at the left sternal border. Examination of the chest revealed no evidence of pulmonary disease.

The abdominal wall was extremely lax. In the region between umbilicus and mid-epigastrium just to the left of the vertebral column most observers palpated a firm

* Received for publication April 22 1936

From the Departments of Medicine and Pathology, Yale University School of Medicine

but vaguely defined, immovable, pulsating mass No other masses were felt There were no other notable findings in the physical examination

Guaiac tests of the stools were positive on several occasions No gross blood or "tarriness" was observed The non-protein nitrogen of the blood was 39 mg

FIG 1 Roentgenogram Calcification of aorta

per 100 c c The Kahn test was negative The red blood cells numbered 4,300,000 per cubic millimeter with 90 per cent hemoglobin and the white blood cells 13,000 with 84 per cent polymorphonuclears, 14 per cent lymphocytes and 2 per cent L M The urine, except for the presence of 15 to 20 white blood cells in the low power field, was negative

At this time the recorded diagnoses included generalized arteriosclerosis with hypertension, and occlusion of the left iliac artery. The pain and abdominal mass were variously interpreted as due to aortic aneurysm, carcinoma of the stomach, pancreas or intestine, or to mesenteric vascular occlusion. Roentgenographic examination demonstrated marked calcification of the abdominal aorta, and the gastrointestinal

FIG 2 Ulcerative atherosclerosis of aorta with obstruction of celiac axis, left iliac and mesenteric arteries, thrombi in superior mesenteric and left iliac arteries

series revealed narrowing of the esophagus (interpreted as due to pressure of the aorta), atony of the stomach with 15 per cent retention of the gastric contents in six hours, and motor delay throughout the small intestine. Failure of the pylorus to dilate with peristalsis was thought compatible with the possible presence of a carcinoma in this region. Three stools in succession were guaiac positive. Nine days

after admission the patient vomited 300 c.c. of material resembling coffee grounds which was weakly positive for guaiac. These findings and the patient's great distress unrelieved by medical therapy induced the decision to perform an exploratory laparotomy.

At operation the peritoneal cavity was found to be devoid of exudate and the color of the intestines to be normal. On the lesser curvature of the stomach near the pylorus there was a tiny, firm zone slightly more vascular than the surrounding tissues to which the omentum was adherent. This was thought to be the serosal aspect of a small ulcer. The abdomen was then closed without further manipulation and the patient was returned to the ward in good condition. Soon thereafter, however, the blood pressure began to fall and the patient died 18 hours after operation despite supportive measures.

At postmortem, incision exposed dull, dark gray peritoneal surfaces. Fibrin covered the intestines, stomach and omentum, particularly at the site of operation. About 100 c.c. of foul dark purple fluid were collected in the right paracecal fossa and pelvis. The serous surfaces of the stomach and inferior surface of the liver were dull gray, those of the entire small intestine and proximal half of the large were dark purple. A loop of ileum adherent to the posterior wall of the bladder was almost black, and so soft that it tore easily in a gentle attempt to loosen the adhesion. The entire gastrointestinal tract was distended with dark red, malodorous fluid.

The mucosa of the stomach was gray, opaque and rugated in the usual fashion. Ulcerations were not found at any point and the vascular area observed at operation did not overlie any mucosal lesion. The pyloric layer of muscle was, however, unusually thick. Microscopic sections showed no evidence of carcinoma. Histologically the gastric mucosa was poorly preserved on account of postmortem change. The wall of the small intestine was so soft as to rupture readily in response to slight stress. A few small superficial ulcers were encountered in the lower ileum. Elsewhere in the ileum and in the large intestine the mucosal surface was opaque and gray-green but not ulcerated. The lower segments of the descending colon and sigmoid were of the usual appearance. The appendix was only 2 cm. in length and teat-like in shape. Its lumen was obliterated. Microscopically the mucosa of the small intestine had undergone complete necrosis. There was marked congestion of the vessels and hemorrhages were prominent at many levels. Cellular reaction was slight and of the polymorphonuclear type. Liver and pancreas grossly and histologically showed no evidence of infarction.

The aorta throughout its length was tile-hard and stiffly maintained its shape when placed upon the table. A remarkable gritty resistance was met in attempting to open the vessel from the rear. The intima in many places was raised by yellow, opaque atheromatous material. Elsewhere it had become superficially ulcerated or infiltrated with calcium now of oyster-shell consistency. About the mouth of the celiac axis was deposited a rosette of very hard material which virtually obliterated the ostium. Just distally, although thick-walled, the vessel was widely patent. The mouth of the superior mesenteric artery likewise was narrowed to an opening of pin-point size by a hard incrustation in its wall. A firm, fresh, laminated, red and gray thrombus completely obstructed the proximal 5 cm. of the vessel. Its branches were dissected and found to be patent although thickened. The inferior mesenteric artery was firm-walled and neither increased nor decreased in caliber. The lumina of the left common and external iliac arteries were reduced to mere crescentic slits because of tremendous thickening of the intima. This consisted of eccentrically split laminae of hyaline connective tissue patchily infiltrated with calcium. Calcification of the irregular media was also prominent. A fresh thrombus partially occluded the left common iliac artery. The corresponding vessels on the right showed similar changes in lesser degree. Their lumina were not obstructed.

The heart weighed 313 gm. It had a deep fatty layer within which the coronaries were palpable as tortuous cords of wire-like firmness. Multiple sections showed marked encroachment upon the lumen by atheromatous plaques, many of which were calcified. Occlusion was at no point complete and no thrombi were found. Calcium containing, hyalinized intimal and medial plaques were demonstrated histologically to have reduced the lumina to narrow channels. In the deeper intimal and medial layers copper-brown refractile hemosiderin granules were evidence of organized hemorrhage. The myocardium, particularly that of the apex and roots of the papillary muscles, showed a moderate degree of fibrosis. There was no evidence of infarction. The aortic valve was slightly thicker than usual but not calcified. Its leaflets were movable and, as far as could be determined, capable of competent closure.

SUMMARY OF CASE

In summary the history is that of a woman of 76 with marked evidence of arteriosclerosis who suffered from intermittent claudication in the left leg, and, latterly, with intermittent sharp abdominal pains coming immediately after eating. At postmortem there was found great narrowing of the left iliac vessels and of the celiac and mesenteric arteries at their mouths. Finally there was a recent thrombus in the last mentioned vessel with an infarct in the region of its distribution.

DISCUSSION

The analogy which the recurrent abdominal pain bears with intermittent claudication in the extremities or with syphilitic or arteriosclerotic narrowing of the mouths of the coronary arteries with angina of effort is plain. The symptom of pain coming so soon after ingestion of food may be accounted for on the basis of the presumably markedly reduced blood supply to the stomach. Occlusion of the celiac axis in the presence of a normal superior mesenteric artery may be without clinical or anatomical result. Collateral circulation usually finds ready access from the superior mesenteric system through the pancreaticoduodenal loop*. Specific instances are presented by Thane and by Hecht. In the present instance, however, the mouth of the superior mesenteric artery was strikingly reduced in diameter by calcium concretions. In addition there was clinical evidence of early cardiac failure (slight edema, breathlessness). These factors tend to reduce the efficiency of a possible collateral blood supply. The exact mechanism responsible for the abdominal pain when food entered the gastrointestinal tract, and for the motor delay is not clear although it has its analogies with intermittent claudication and with angina.

Although frequent reference is made in general articles (e.g., in the excellent one of Klein) to the occurrence of chronic abdominal pain in vascular disease specific examples with data relative to findings at postmortem are rare, nor do they supply sufficient material for the description of clear-cut clinical entities except in the broadest suggestive outlines. The accompanying tabular summary includes only those cases in the literature in which the findings at necropsy are stated.

* In the event of complete occlusion of the superior mesenteric artery, however, sufficiency of the collateral circulation is rare. There are, nevertheless, several striking exceptions. Nazari renders an account of six patients in whom old thrombi were seen to occlude the trunk of the superior mesenteric artery although the intestines were not infarcted. In one of these the inferior mesenteric artery was twice its usual size. A very remarkable example of a normal intestinal tract in the presence of obliteration of both the celiac and mesenteric trunks was described by Chiene in a dissecting room subject (1868). The blood supply was derived by anastomosis of the gastrointestinal vessels with greatly enlarged lumbar arteries.

Chronic Cases of Abdominal Pain Associated with Vascular Disease

Sex and Age	Chief Symptoms	Duration	Laboratory and Physical Findings	Course	Pathology	Source and Date
Female 48	Repeated attacks of severe pain in the right hypochondrium Profuse diarrhea, "coffee ground" stools Numbness of left leg	8 mos "of late"	Abdominal tenderness and distention Visible peristalsis Cangrene of left foot	Death soon after amputation of left leg	Laminated clot about the mouth of the superior mesenteric artery Entero colic and entero-enteric fistulas Thrombosis of left common iliac artery and vein	Howse 1878
Male 40	Intense abdominal neuralgia	5 yr		Found unconscious	Calcified mesenteric lymph nodes compressing the trunk of the superior mesenteric artery Thrombosis of superior mesenteric artery Hemorrhagic infarct of intestine	I epine quoted by Adenot 1890
Female 55	Constipation relieved only by enemata Pain in epigastrium, right hypochondrium and umbilicus, recently of special intensity and coming after meals Almost continuous pain in the lower abdomen	5 yr 4 yr To 6 mo before admission Past 6 mo	Vital signs normal Abdomen, soft, sensitive in the epigastrium	Operation gall-bladder showing slight chronic cholecystitis removed No relief of symptoms Death suddenly 1½ mo after operation	Complete obliteration of superior mesenteric artery by an old organized thrombus Fibroid hemorrhagic peritonitis Infarct of small intestine	Schnitzler 1901

Chronic Cases of Abdominal Pain Associated with Vascular Disease—*Continued*

Sex and Age	Chief Symptoms	Duration	Laboratory and Physical Findings	Course	Pathology	Source and Date
Male 55	Pain in region of umbilicus and in right lower quadrant, severe distention 1½ hr after each heavy meal Constipation relieved by enemata	2 years Several remissions Present attack 3 mo	Marked distention of abdomen 2 to 3 hrs after eating	Death 1½ days after exploratory laparotomy	Extensive arteriosclerosis of superior and inferior mesenteric arteries including their finer branches, distention of entire gastrointestinal tract Peritonitis	Ortner 1902
Male 41	Abdominal pain, nausea and feeling of rapid fullness after eating Admitted in emergency on account of attack of extremely severe abdominal pains, blood in vomitus and stools	21 months	Wassermann reaction positive Normal gastric analysis Pallor, sweating Slight diffuse distention Slight muscular guarding W B C 18,000 Temp 38.2°C	Operation performed under diagnosis of perforated gastric ulcer Resection of 1 meter of upper ileum Patient died soon after	Thrombi, sessile upon ulcers of aorta, one of which acted as a flap valve over the mouth of the superior mesenteric artery	Storring 1934

Clinically pain was the most prominent symptom. The duration varied from eight months to five years. Most often it was in the periumbilical region or right side. In three instances it was stated to be associated with ingestion of food—appearing one to three hours later. Moynihan remarks that “the greater suffering caused by heavy meals as compared with the less suffering after light meals is most significant.” Distention accompanied the pain to a striking degree in one patient, and a feeling of fullness and of nausea in another. Two suffered from diarrhea, but in two constipation relieved only by enemata was the characteristic symptom. Vomiting was rare. The most constant recorded features on physical examination were abdominal tenderness (four patients) and distention (three patients). The abdomen was soft to palpation.

The anatomical changes were diverse. In one case a laminated clot narrowed the mouth of the superior mesenteric artery, in another a thrombus sessile upon an atheromatous ulcer acted as an obstructing valve and in Schnitzler's patient an old thrombus completely occluded the trunk of the vessel. In one post-mortem examination calcified mesenteric lymph nodes were seen to compress the superior mesenteric trunk. In Ortner's case there was extreme arteriosclerosis of the superior and inferior mesenteric arteries including their finer branches. It is of interest that infarction of the small intestine with peritonitis was the terminal event in three of five recorded cases and also in the subject of the present report. Operation was followed by death in all of the four patients on whom it was performed.

More difficult to interpret are the published clinical impressions without necropsy material (Gilbride, Meyer, Goodman, Hamburger). Their chief value is in the light that they shed on possible treatment. The clinical descriptions are in agreement with those summarized in the table. Gilbride emphasizes the tenderness of the abdominal aorta, the epigastric or umbilical pain that may increase during digestion, upon exertion, in association with emotional disturbances or upon assumption of the horizontal position. Remarkable is the relief reported to be obtainable with various vasodilators. Hamburger has used nitroglycerine in doses of gr 1/50 with success as has Gilbride. Buch and the latter recommend strophanthus and theobromine sodium salicylate.

Among the diseases to be considered in the differential diagnosis are the colics, renal, biliary, intestinal and that associated with plumbism, peptic ulcers, abdominal aneurysms, gastric crises of tabes, and above all carcinoma where the possibility of relief by surgery exists. True anginal heart disease with pain referred to the abdomen is usually accompanied by substernal pain (Buch). The use of vasodilators may serve as a therapeutic test, but all available physical and laboratory methods should be employed to rule out non-vascular disease.

CONCLUSIONS

The symptoms associated with abdominal arteriosclerosis, as shown by the five cases reported in the past and the present case, are usually of upper abdominal pain sometimes associated with the ingestion of food, abdominal tenderness and, to a lesser degree, distention and feeling of fullness. Either constipation or diarrhea may be present. Vascular disease should be more often considered in the differential diagnosis of chronic abdominal pain than heretofore. This is all the more important because of the great danger of operation in such

cases and the possibility of securing relief by the use of vasodilators. It is obvious that further study with careful clinical, roentgenographic, electrocardiographic and necropsy reports are necessary.

Note Since this paper has gone to press, another article on this subject has appeared DUNPHY, J. E. Abdominal pain of vascular origin, *Am Jr Med Sci*, 1936, cxcii, 109-113.

PRIMARY PNEUMOCOCCIC PERITONITIS, RECOVERY OF THE ACUTE SEROUS TYPE FOLLOWING TYPE I SERUM TREATMENT WITHOUT SURGICAL INTERVENTION*

By MANUEL M GLAZIER, M D, BERNARD I GOLDBERG, M D, and
A A WEINSTEIN, M D, *Boston, Massachusetts*

PNEUMOCOCCIC peritonitis is comparatively uncommon and bears a grave prognosis. It is generally divided into two types, primary and secondary. The primary type is characterized by involvement of the peritoneum without any discernible focus of infection and it tends to run one of two courses. The most common course is an acute diffuse serous peritonitis that usually ends quickly in exitus. The second course results in a localized and circumscribed abscess of the peritoneum and is associated with a more favorable prognosis. In the secondary type of pneumococcic peritonitis we find an antecedent or coincidental source of infection, usually the respiratory tract, with subsequent development of peritonitis.

In primary pneumococcic peritonitis, the majority of cases have been treated surgically with a very high mortality, especially in the acute diffuse type. Lipschutz and Lowenburg¹ had a mortality of 100 per cent in a group of 13 cases reported in 1926.

In our review of the literature, recovery in a patient with the acute serous type of primary pneumococcic peritonitis, without surgical intervention, and with specific serotherapy has previously not been reported. The purpose of this paper is to report such a case with dramatic recovery following the therapeutic use of specific serum.

CASE REPORT

M M, female, aged five, entered the Beth Israel Hospital on January 6, 1935, complaining of abdominal pain and fever.

Past History. This included whooping cough at the age of 10 months, measles at the age of two years, pneumonia one year previously. The patient was known to be sensitive to various foods and had received diphtheria toxin and antitoxin immunization. There was a family history of bronchial asthma. According to the parents, the child developed an upper respiratory infection 10 days before admission, characterized by a slight non-productive cough, unassociated with temperature or malaise. Seven days before admission, the child complained of twinges of abdominal pain, not severe in nature, nor incapacitating. This episode was repeated five days before admission. Throughout this period she was up and about, attending school. During the evening prior to admission, the child complained of a "bellyache." On the morning of admission, she ate a good breakfast, and had no complaints, but in the afternoon she developed anorexia and lassitude and a temperature of 104.5° F by rectum. During the inspection of the throat the patient vomited for the first time. The vomiting was non-projectile in nature. In the afternoon the patient suddenly developed severe generalized abdominal pain and was found to be writhing in agony. These cramps continued intermittently until 6 p.m. The child became extremely toxic and was referred to the hospital.

* Received for publication June 17, 1936.

From the Departments of Pediatrics and Medicine, Beth Israel Hospital and Tufts College Medical School.

Physical examination revealed a well developed, well nourished child with flushed face lying in bed, talkative and cooperative Temperature 105° F, respirations 30, pulse 150 The throat showed only mild injection without exudate The examination was otherwise negative except for a distended abdomen showing moderate involuntary spasticity most severe in the right lower quadrant By rectal examination, there was more tenderness in the right lower quadrant than the left

CHART 1

Clinical Course Upon admission (evening of January 6, 1935) patient was put in high Fowler's position All fluids by mouth were restricted and the water balance maintained by an intravenous drip of 2.5 per cent glucose in normal saline solution Distension was controlled by flaxseed poultices and rectal tube Morphine sulphate gr 1/24 was given subcutaneously every three hours Admission blood culture (read after 14 hours' incubation) showed many colonies of gram positive diplococci On typing, this was found to be Type I pneumococcus The admission urine showed a

specific gravity of 1.036, v. s. t. of albumin, 2.5 per cent sugar, 3 plus acetone, one to three pus cells per high power field. The admission white count was 14,400 per c. c. The admission red count was 4,100,000 per c. c., hemoglobin 80 per cent. Throat smear on admission showed many gram positive diplococci and streptococci. Roentgen-rays of the chest were negative.

The next day (January 7, 1935), the temperature rose to 106.5° by rectum, pulse 172, respirations to 44. The patient was markedly dehydrated, wildly delirious, toxic and completely irrational. The patient was controlled by the constant care of extra nurses daily (two on a shift). Paraldehyde was given by rectum for restlessness. The white blood count rose to 18,400. Stool examination showed no blood on Guaiac test. The abdomen was definitely more spastic throughout with increased resistance in both lower quadrants where the patient also, in her more lucid moments, noted more pain on pressure. The heart and lungs were negative. During the evening the patient was started on antipneumococcus serum therapy as described in the chart. The intravenous drip of 2.5 per cent glucose in salt solution was continued and two clyses of 1000 c. c. of saline and glucose were also given.

On January 8, 1935 (the second hospital day), the day after the administration of serum, the abdomen was somewhat softer. The patient was rational, no pain was noted on pressure about the umbilicus. There was some tenderness in both flanks, however, and both lower quadrants. The temperature, pulse and respiration dropped to 102° (by rectum), 140 and 25, respectively. The intravenous use of serum was continued as described in the chart.

On January 9, 1935 (the third hospital day), the patient continued rational and became brighter, more cheerful and talkative. Intravenous drip was discontinued and the patient was allowed cracked ice and sips of water as desired. The intravenous use of serum was continued. The temperature remained about 102° rectally and the pulse went down to 130. The second blood culture was negative (no growth on culture media after nine days). The white count dropped to 9,100 per c. c. in the morning and to 7,700 in the evening. The patient's fresh blood serum agglutinated Type I and Type II pneumococcus microscopically. Type I pneumococcus was agglutinated in dilution of one to two only. On January 10, 1935 (the fourth hospital day) the patient developed a cough and hiccup on respiration. Roentgen-ray of the chest was negative. There was tenderness at the right and left upper quadrants. Respiration 48. (See clinical chart.) During the next four days the spasm and tenderness in the abdomen diminished so that there was some residual tenderness only in both lower quadrants. The abdomen became "doughy" to touch, abdominal distention was present and a fluid wave could be felt. Distention was controlled by flaxseed to the abdomen and by a rectal tube. The temperature remained 102° F rectally. The patient continued bright, talkative and cheerful. Fluids by mouth, up to three ounces at a time, were well tolerated. The final dose of serum (8 c. c.) was given intravenously. A third blood culture taken on this day proved to be negative. The patient's fresh blood serum showed complement in low titer as measured by activation of sheep cell hemolysis. Fresh blood serum agglutinated Type I and Type II pneumococcus microscopically and macroscopically. The serum agglutinated Type I pneumococcus in dilution of 1-4, but failed to agglutinate Type II pneumococcus. One liter of urine was concentrated to 5 c. c. From this an attempt was made to recover specific substances, but the alcohol insoluble material contained no substances which would precipitate Type I antipneumococcus serum*. The white count was normal. The urine showed no sugar, albumin or acetone, sediment negative.

On January 11, 1935 (the fifth hospital day) the patient continued to improve, the temperature remained about 100° F rectally, and most of the abdominal signs and symptoms disappeared. The white count was normal and the urine was negative.

* We are indebted for the performance of these tests to Dr. Maxwell Finland, who also assisted in directing the sero-therapy.

On January 12, 1935 (the sixth hospital day) the patient's temperature dropped to 98.6° F rectally in the morning. In the afternoon, the patient developed serum sickness, characterized by fever (104.4° F by mouth), arthralgia and rash. This subsided in four days. Further convalescence was uneventful with blood and urine normal and the patient was discharged on January 22, 1935, the sixteenth hospital day.

COMMENT

There have been many differing views regarding the mode of infection in primary pneumococcus peritonitis. The peritoneum may presumably become infected (a) through the gastrointestinal tract, (b) by way of the blood stream, (c) from the vagina through the fallopian tubes to the pelvic peritoneum. The evidence in favor of the transdiaphragmatic lymphatic route is meager. The direction of the lymphatic drainage in the region of the diaphragm has been shown to be upwards. There have been some proponents of the theory that pneumococci reach the peritoneum by egress from the intestinal tract. However, Jensen,² Wolfsohn,³ and McCartney and Fraser,⁴ were unable to produce peritonitis by feeding cultures of pneumococci to mice, even though the former demonstrated pneumococci in the intestinal wall. Obadalek⁵ and Koennecke⁶ concur in the belief that pneumococci in feces may produce peritonitis by contamination of the genital tract in females. Rischbieth⁷ and others advance the view that pneumococcal peritonitis is always secondary to a septicemia. Pneumococcal septicemia, however, is a very frequent concomitant of lobar pneumonia, which is very rarely complicated by peritonitis. Rolleston⁸ found 11 cases of peritonitis in 4454 cases of pneumonia, Rischbieth only one case in 6000 pneumonias and Elkin⁹ three in 1908 cases. Blake and Cecil¹⁰ were unable to produce pneumonia or peritonitis by intravenous injection of pneumococci, the animals dying of septicemia. On the other hand, Jensen¹ showed that pneumococci reached the blood stream in a rabbit a few minutes after intraperitoneal injection. These experiments were confirmed by McCartney and Fraser. Apparently other factors in addition to the mere presence of pneumococci in the blood stream are necessary to produce peritonitis. Peiser¹¹ suggested that the uninjured peritoneum was impermeable to the invasion of organisms from the blood stream. This may account for the increased frequency of peritonitis in association with nephrosis with ascites. McCartney and Fraser⁴ made a detailed study of the mode of infection and found no evidence in favor of either the hematogenous or enterogenous theories. They regard all cases of primary or idiopathic pneumococcal peritonitis as arising from the genital tract and of necessity therefore, limited to the female sex. In their study of 56 cases, they claim that the 12 cases occurring in boys were all of the secondary type. Barrington-Ward¹² and others, however, have reported cases in boys. In one case reported by Leonardo, the disease developed in a woman who had had an amputation of the uterus 15 years previously. Nevertheless, the overwhelming incidence in girls points strongly toward the genital tract as the chief source of infection with an occasional case arising via some other route.

Diagnosis. The primary type occurs most frequently in children between the ages of two and seven. The disease is usually characterized by an abrupt onset of severe abdominal pain, chiefly localized in the lower abdomen. Vomiting and diarrhea may occur, the latter sometimes associated with tenesmus. Hyperpyrexia, prostration, delirium and dehydration are other features. Cases

with a more chronic course have been reported with and without an associated intraabdominal localization of the purulent process. As a rule the more chronic type of case has a much better prognosis. A milder form with a spontaneous recovery has also been observed and described as an abortive type¹³. In suspected cases immediate blood culture is of paramount importance since many of these cases are associated with a pneumococcal septicemia. We have already mentioned that experimentally the blood stream shows the presence of organisms within a few minutes after intraperitoneal injection. Frequent smears from the culture medium should be made. As soon as organisms are discovered typing should be at once performed.

In the differential diagnosis one must consider chiefly acute appendicitis with or without perforation and subsequent peritonitis, and peritonitis due to the streptococcus. In most cases the diagnosis of appendicitis was made when the patients were first seen, and not until after an examination of the abdominal fluid at operation was the correct diagnosis made. In suspected cases abdominal fluid may be obtained by abdominal paracentesis. In 100 cases Neuhoff and Cohen¹⁴ demonstrated that this was an innocuous procedure. Other authors advocate puncture of the pouch of Douglas in females¹⁵. In some cases pneumococci have been found in vaginal smears.

An attempt to type the pneumococcus should always be made immediately irrespective of the source of the organism. There are no reliable statistics to indicate the actual frequency of the various types of pneumococci found in primary pneumococcal peritonitis. Prior to 1926, Leonardo¹⁶ found a total of 22 cases in the literature where the organisms were typed, 16 were Type I, 3 Type II and 3 Type IV. Since then the marked paucity of complete bacteriological studies has been striking, most of the authors being content with determining the generic organism.

The indefinite character of the patient's symptoms prior to admission precludes any estimation as to the time of onset of the peritonitis. This child had a history of a mild upper respiratory infection about a week preceding the onset of the peritonitis and examination of the throat failed to reveal any definite abnormality. The negative physical examination of the chest and the repeated roentgen-rays ruled out the lungs as the source of the infection. However, the patient's course was fulminating with hyperpyrexia during the day of entry.

The diagnosis was based upon (1) history of an upper respiratory infection (present in 90 per cent of the cases reported by Lipshutz and Lowenburg¹) (2) Onset of severe abdominal pain with signs of an acute "surgical" abdomen (3) Temperature that varied between 105 and 106.6° F rectally (4) Rapid prostration and delirium (5) Positive blood culture (Type I pneumococcus).

It was the unanimous opinion of all who saw the patient that surgical intervention was not indicated*, it was felt that her condition was so critical that an operation would be fatal.

In view of the presence of Type I pneumococci in the 14 hour blood culture immediate sero-therapy was instituted with the results indicated in the clinical course and in the chart.

Cases have been reported where a Type I pneumococcus was found at operation and sero-therapy was instituted after operation¹⁷. We have been un-

* Dr C G Mixter and Dr D D Berlin as surgical consultants and Dr E H Place as consulting pediatrician were all opposed to surgical intervention.

able, however, to find a case of primary fulminating pneumococcic peritonitis (i.e., acute serous type) treated solely by specific serum. In 1924, Struther¹⁸ stated that he "was able to find no information on the use of specific sera in pneumococcic peritonitis." Although Barrington-Ward suggested the use of specific serum in the outline of treatment, none of his cases had received serum. Fricke¹⁹ reported one case, an adult, of the more favorable chronic type, who was given serum and recovered without operation. He does not state how long the condition existed before giving the serum. The clinical condition of our patient was so critical and her response to serotherapy was so pronounced that it is unlikely that a spontaneous remission in the disease had taken place.

Serum Chart

Condition			Improved
Diagnosis			Idiopathic pneumococcus Type I peritonitis

The usual leukocytic response in pneumococcic peritonitis resembles more that of an acute septic type of hyperleukocytosis than the moderate elevation found in the ordinary cases of acute appendicitis. Glass²⁰ commented on the frequency with which counts of 30,000 or more are encountered in pneumococcic peritonitis. Gibson²¹ stressed the extraordinarily high leukocyte count with a high percentage of polymorphonuclears as a valuable point in differentiating this type from the appendiceal and non-pneumococcic forms of peritonitis. The white blood cell counts in this case did not conform to Gibson's formula, the highest being 18,400. However, Lazarus²² has noted similar low counts in several patients critically ill with the acute serous type of primary pneumococcic peritonitis.

SUMMARY

Primary pneumococcic peritonitis is a disease occurring chiefly in female children. The mortality rate is very high, both in operated and unoperated cases, especially in the acute serous type of primary pneumococcic peritonitis. A case of this severe type of primary pneumococcic peritonitis with Type I pneumococcic septicemia which responded to the administration of specific serum, is reported. Complete recovery without complications ensued and the patient was discharged in 16 days. In view of the fact that pneumococci reach the blood stream early in the course of this infection, repeated blood cultures are indicated in every patient in the hope of finding a type amenable to specific sero-therapy.

CONCLUSIONS

Early specific sero-therapy in the treatment of primary pneumococcus peritonitis, we believe, offers a non-surgical method of attack, which may prove valuable in selected cases and should be given wider trial.

THROMBOPENIC PURPURA ASSOCIATED WITH CATARRHAL JAUNDICE REPORT OF A CASE

By HOWARD L ALT, M D, and ROY L SWANK, M D, *Chicago, Illinois*

A PATIENT has been observed in whom an acute thrombopenic purpura occurred simultaneously with an acute catarrhal jaundice. The case is reported because of its uniqueness † and because of some of the theoretical implications involved.

CASE REPORT

A O, a single, male medical student, aged 24, entered the Passavant Memorial Hospital on November 3, 1934, complaining of malaise, epistaxis and jaundice.

* Received for publication August 17, 1936

From the Department of Medicine Northwestern University Medical School

† No similar case report could be found in the literature

History The family history and past history were irrelevant. The present illness began October 1, 1934, when the patient contracted an upper respiratory infection. Following this, he felt below par. On October 30, he had loss of appetite, muscular aching, constipation, and discomfort in the abdomen. The next day the urine was highly pigmented, and the stools lighter than normal. The following day (November 1), the patient noticed slight icterus and remained in bed. On November 2, he had nose bleeds, and petechial spots appeared on the trunk. He continued to have light stools and constipation, but the aching and abdominal discomfort subsided. The patient was admitted to the hospital the next evening. No drugs had been taken during this illness.

Physical Examination The physical examination revealed a well nourished, somewhat apprehensive young male who did not appear to be very ill. There was bleeding from the left nostril. The sclerae and skin were moderately icteric. Numerous petechial hemorrhages were present on the lips and gums, and were also scattered all over the body. Subcutaneous hemorrhage was not readily produced by pinching the skin. The heart and lungs were normal. The liver was not palpable, but the tip of the spleen was palpated at the costal margin on deep inspiration. The temperature was 98.8° F, pulse 80, and respiration 20. The blood pressure was 114 mm of Hg systolic, 70 mm diastolic.

Laboratory Examination The significant laboratory data are best presented in tabular form (see table). It is apparent that the laboratory signs were those of thrombopenic purpura with bleeding from the kidneys and the gastrointestinal tract. The direct Van den Bergh test showed a positive prompt and negative delayed reaction, while the indirect quantitative test and icterus index were markedly increased. The bromsulphalein test showed a marked retention of the dye when performed on the fifth day, while the levulose tolerance was practically normal when first studied on the sixth day after admission.

Additional laboratory data not listed in the table revealed the following: Reticulocyte counts on two occasions, less than 1 per cent. Erythrocyte volume index, 106. Fragility test, within normal limits. Differential polymorphonuclear neutrophiles, band forms 0, segmented forms 67 per cent, lymphocytes 21 per cent, monocytes 12 per cent. Coagulation time, 2 minutes. Urine pigmented, contained erythrocytes. Feces dark brown, HgCl₂ test for urobilin and bilirubin negative, benzidine test markedly positive. Blood calcium, 10.9 mg per 100 cc.

On the fourth day after admission, a tube was inserted into the duodenum, and a thin greenish mucoid secretion was obtained after administration of 100 cc of magnesium sulphate. Inoculation of the patient's blood into a guinea pig showed a negative test for Weil's disease.

Course and Treatment No fever or tachycardia occurred at any time during the course of the disease. On the second day after admission (November 5), the patient received a transfusion of 250 cc of citrated blood, and the following day 50 cc of whole blood into the buttocks. Beginning November 5, parenteral liver extract (1 cc derived from 33 1/3 gm liver*) and calcium gluconate and viosterol were given daily. For three days after admission, the petechiae increased, bleeding from the nose became more severe, and there was an increase in bleeding from the kidney and gastrointestinal tract. On November 6, the patient began to improve, and by November 8 all gross bleeding had stopped. Clinical and laboratory signs of the thrombopenic purpura rapidly returned to normal. At the same time, there was continuous improvement in the jaundice. The patient was discharged from the hospital November 24, three weeks after admission, in excellent condition. There has been no recurrence of symptoms up to the present time, one and one-half years after the illness occurred.

* Lederle's Concentrated Liver Extract

COMMENT

The thrombopenic purpura and jaundice in this patient began at about the same time and ran a similar course. The improvement that occurred following the blood transfusion and liver therapy may have been a coincidence. From the clinical picture, the jaundice was apparently of the catarrhal type. Whether actual liver damage occurred or not is uncertain. Many authors^{1, 2, 3, 4, 5} have reported a decreased galactose tolerance in patients with catarrhal jaundice and have usually interpreted this as being evidence of parenchymatous liver disease. In our case, the levulose tolerance curve was practically normal when first studied on the ninth day of the illness. This does not preclude an earlier pathologic curve, as Jolliffe⁶ has shown that the decreased levulose tolerance in catarrhal jaundice may return rapidly to normal shortly after the blood bilirubin reaches its peak.

There are several theories that might explain the etiologic relationship between the thrombopenic purpura and the catarrhal jaundice, namely, (1) they may have occurred independently, (2) they may have been caused by the same etiologic process, and (3) the purpura may have been secondary to the catarrhal jaundice. The latter theory will be considered further, because certain reports in the literature suggest that thrombopenia may be related to liver disease.

The bleeding tendency that often accompanies jaundice and liver disease is not usually of the thrombopenic type. However, exceptions to this rule have been reported. Loeper and DeSeze⁷ observed a patient in whom purpura occurred along with metastatic carcinoma of the liver. The patient had numerous petechiae, a prolonged bleeding time, a normal coagulation time, and a delayed clot retraction. The platelet count was not reported. Willebrand⁸ described three cases in which thrombopenic purpura was associated with liver disease. Two of his patients had metastatic carcinoma of the liver, and a third had an acute yellow atrophy of the liver following salvarsan therapy. Recently, Abram⁹ discussed this subject under the title of hepatic purpura. He described two cases, one of atrophic cirrhosis and another of spleno-hepatic disease of syphilitic origin. Both patients had purpura, a prolonged bleeding time, a positive tourniquet test, and non-retraction of the clotted blood. The platelet count was not reported in the first case, but was 82,000 per cu mm in the second. Splenectomy was specific in controlling the hemorrhagic tendency in both cases. Abram believes that true purpura in liver disease is due to involvement of the "spleno-reticulo-endothelial" system and is not due to the liver insufficiency per se.

Very few data on the platelet count in liver disease are available in standard reference books. Jones and Minot¹⁰ estimated the number of platelets on blood films from patients with catarrhal jaundice and found them to be within normal limits. During recovery from the disease, there was an increase in the thrombocytes. Weil et al¹¹ reported a diminution in platelets in 18 out of 20 patients with liver lesions. Their series consisted mainly of cases of cirrhosis and chronic congestion of the liver. King¹² found a thrombopenia in 20 per cent of patients with portal cirrhosis of the liver. Fellingner and Klima,¹³ studying a group of patients with cirrhosis of the liver, frequently found a decrease in platelets which was related to the degree of liver involvement. In one advanced case, the platelet count was 20,000 per cu mm, the bleeding time was

prolonged, and the clotting time was normal. The thrombocyte level is said to be low in acute yellow atrophy of the liver^{14, 15}. Higgins and Stasney¹⁶ reported a decrease in platelets to one-third of normal in rats with cirrhosis of the liver produced with carbon tetrachloride. A diminution in the leukocytes or erythrocytes may also be associated with hepatic disease. Leukopenia is reported to occur in catarrhal jaundice¹⁷ and cirrhosis of the liver,^{12, 18} while anemia is frequently associated with various types of liver disease¹⁹.

The cause of the decrease in thrombocytes in liver disease is not apparent. As Abram⁹ has suggested, the decrease might well be related to an associated pathologic process in the spleen rather than to the liver condition itself. The influence of the spleen on the blood platelets is evident in such diseases as thrombopenic purpura and splenic anemia where splenectomy is followed by thrombocytosis. Another possible mechanism in the pathogenesis of the thrombopenia in liver disease might be through the deficiency of a nutritional factor necessary for thrombopoiesis. For example, the macrocytic anemia of advanced cirrhosis is thought to result from the inability of the liver to store a necessary hemopoietic principle¹⁹.

From the evidence presented, it seems possible that the thrombopenic purpura in the patient reported could have been secondary to the catarrhal jaundice. A case of this type is a stimulus to further clinical and experimental observations.

SUMMARY

1. A case is reported in which thrombopenic purpura occurred simultaneously with catarrhal jaundice.

2. Evidence is presented which suggests a relationship between thrombopenia and liver disease.

CHLOROMA, REPORT OF A CASE¹

By HAROLD R ROEHM, M D, F A C P, AARON RIKER, A B, M D, and
RICHARD E OLSEN, Sc D, M D, *Birmingham, Michigan*

CHLOROMA is not a common form of malignant tumor Washburn¹ in a review of the literature through June 1929 found 162 cases Since that time 32 more have been reported, bringing the total to 194

Dock and Warthin² in 1904 published an exhaustive study of the clinical and histological features of the disease Their conclusion was that, "chloroma is a tumor-like hyperplasia of the parent cells of the leukocytes, primarily in red marrow, the periosteum being secondarily involved"

In the past, opinions have been divided concerning the lymphatic or myelogenous origin of the neoplasm, but the general opinion at present would indicate that the majority of chloromas are myelogenous in origin

The prognosis of patients with chloroma has been universally bad with two exceptions The first, reported by Lecène,³ was a case of a tumor of the humerus, which was treated by amputation and roentgen-ray therapy, the second, reported by Washburn,¹ was a case of tumor of the left frontal bone of the skull, with operative removal and subsequent roentgen-ray therapy Swanson,⁴ Rosenblum,⁵ Doub and Hartman,⁶ and others failed to find roentgen therapy to be of value in influencing the final outcome of the disease

We believe the following case of chloroma cannot be classified as either lymphatic or myelogenous in origin as the tumor cell is a primitive blast which might conceivably differentiate into either a lymphocyte or a myelocyte

CASE REPORT

Elizabeth S, white female, aged 13 years, was brought to the hospital February 21, 1936, because of weakness, anemia, and vomiting She had been irrational for the preceding 24 hours

* Received for publication August 7, 1936

FIG 1 No 1 Chloroma Neoplastic cells in a lymph node (× 2070)
No 2 Endothelial phagocytes and tumor cells in the dura mater (× 2070)

In November 1935, the patient noticed swelling of the upper eyelids, severe enough at times to tightly close them. She rapidly became weak and pale. She complained of pain referred to the navel and vomiting. In December 1935, the vomiting grew worse, again accompanied by umbilical pain. In January 1936, her right eyelids suddenly became black and this was followed by the same phenomenon in the left eyelids a few days later.

January 10, she was taken to a hospital where she was diagnosed as suffering from malformations of both kidneys. She was given two blood transfusions with only transient benefit. Frequent nasal hemorrhages began. No bowel movements could be obtained. She was discharged January 25, slightly improved.

On February 12, 1936, persistent vomiting began and continued to the time of admission (February 21). There was a familial history of cancer.

Physical examination. The patient was extremely anemic and emaciated, irrational, and apparently almost deaf. She appeared to be nearly blind. The upper eyelids showed moderately firm swelling with dilated superficial veins. There was no exophthalmos. Crusts of dried blood were present in both external nares. The cervical, axillary, and inguinal glands were all palpable, discrete, and bean sized. There was an apical systolic cardiac murmur probably due to the anemia and not organic in origin. Examination of the chest revealed no evidence of disease. The abdomen was scaphoid with almost no panniculus. Tenderness was present in both upper quadrants but particularly the right. A smooth mass occupied the upper right quadrant from the ribs down to the level of the umbilicus. This mass was flat to percussion and poorly defined in outline, and appeared to be a greatly enlarged liver. The remainder of the examination was essentially negative.

Laboratory examinations. Ten consecutive urine analyses showed positive albumin, a trace of sugar, and fields full of granular casts and white and red blood cells. The specific gravity was fixed at 1.010. A blood count (February 21) showed hemoglobin 32 per cent (Dare), red blood cells 650,000 and white blood cells 10,100 per cu mm, polymorphonuclear neutrophils 47 per cent, lymphocytes 48 per cent, monocytes 5 per cent. Nothing abnormal was noted about any of the white blood cells. The sedimentation rate of the red blood cells was 44 mm in 60 minutes (Cutler). Blood non-protein nitrogen was 28.5 mg per 100 cubic centimeters. The stools contained four plus occult blood. The blood Kahn was negative.

Eye examination (February 27) revealed the following. The pupils reacted sluggishly to light and accommodation. They were dilated under homatropine and cocaine. No protrusion, nystagmus or paralysis of either eyeball was noted. The anterior and posterior chambers and lens were clear. Both eyes showed marked vitreous opacities. The fundus examination of the right eye showed over four diopters choking of the disc, with the vessels of the retina engorged and tortuous. There were marked masses of hemorrhage throughout the retina with small white areas noted in the center of the masses. The largest mass of hemorrhage was in the superior temporal portion of the fundus. A definite cherry-red spot showed around the fovea. The fundus examination of the left eye showed the same characteristics, except that the largest mass of hemorrhage was found posterior and towards the temporal side. A cherry-red spot also showed around the fovea and about two diopters choking of the disc was noted.

Roentgen-ray examination by Dr. J. E. Church (February 22, 1936) showed that the left lung field was a trifle more radiolucent than the right although no definite pathologic changes could be defined. An attempt was made to examine the upper gastrointestinal tract but the patient was non-cooperative and only a minute amount of barium was taken. A single anterior-posterior film was taken showing some of the meal had passed into the small intestine, which suggested that there was no obstruction of the pylorus. Some flakes of barium or bismuth which were found in

FIG 2 No 1 Arteriole filled with tumor cells at the edge of a cerebral vacuole ($\times 230$)

 No 4 Peroxidase granules present in a polynuclear leukocyte but absent in the tumor cells ($\times 2070$)

the region of the rectum were due to some former examination or medication. The left kidney was not outlined, but the right was well defined, appearing as if it might be a little larger than normal.

A provisional diagnosis of lymphosarcoma with metastases to the brain was made as a result of the examinations.

Course of the disease. Twenty-four hours after admission the patient was given a transfusion of 500 cubic centimeters of whole blood with some transient improvement. The temperature ran an irregular course from 100° to 104° F. Five hundred cubic centimeters of 5 per cent glucose in normal saline were given twice daily. This was useful in controlling the persistent vomiting. Frequent hemorrhages from the nose occurred daily. The patient rapidly failed in spite of supportive treatment and expired March 1, 1936, nine days after admission.

Autopsy report. The autopsy was done one and one-half hours after death. External examination showed a female at the age of puberty who was markedly emaciated and very pale. There was moderately firm swelling of the upper eyelids.

Internal examination revealed about two liters of clear yellow fluid in the abdominal cavity. The liver and spleen were much enlarged. The mammary gland tissue was a bright olive green bilaterally. The costal cartilages cut with difficulty. The periosteum on the internal surface of the sternum and ribs was thickened and was almost uniformly bright green and the thymic fat in the anterior mediastinum was of the same color. About one liter of orange colored fluid was present in each pleural cavity and 100 cubic centimeters in the pericardial sac. There was one green spot on the anterior surface of the pericardial sac. The heart blood clots were maroon. No green areas were seen in the myocardium. The gross cardiac lesions were limited to a rather marked sclerosis of the aortic ring, involving the orifices of the coronary arteries. The lungs were bizarre in appearance having many reddish-purple and a few green slightly elevated areas over the surfaces of both lungs, the largest of these was not more than two centimeters in diameter. The peribronchial lymph nodes were uniformly olive green in color and varied in size up to one centimeter in diameter. The lungs were nodular on palpation, the nodules being the discolored areas described. On the cut surface there was revealed a bilateral bronchial pneumonia.

The liver measured 25 by 24 by 8.5 centimeters and was a maroon color. On the cut surface no gross tumor nodules were found and the liver lobules were distinctly outlined. The spleen measured 16.5 by 9 by 4.5 centimeters. The capsule was purple and tense. On the cut surface there were greenish spots scattered at intervals, none of them being over one-half centimeter in their greatest diameter. The peri-esophageal lymph nodes were green but the remainder of the gastrointestinal tract showed no green areas, and the mesenteric nodes though enlarged up to a maximum of 3 centimeters in size were maroon in color. The stomach showed petechial hemorrhages. The retroperitoneal lymph nodes were 2 centimeters in length and were olive green. The periaortic nodes had the same appearance.

The kidneys were studded with subcapsular green nodules up to 1 centimeter in diameter. The adrenals were small but showed no discolorations. The uterus showed several greenish nodules on the serosal surface, and the endometrium was olive green. The ovaries showed no gross pathologic change. The vertebral bodies had some greenish spots on their anterior surfaces and were unusually soft so that they could be cut easily with a knife. The ribs were almost as soft as the costal cartilages, and their bone marrow varied from maroon to olive green. The bone marrow of the sternum was maroon.

The periosteum of the skull was green near the midline, and was slightly thickened. The bones of the skull were harder than the ribs and vertebral bodies but still were softer than normal and their bone marrow was brown. The dura mater was thickened to one-half centimeter near the midline and was olive green. The

FIG 3 No 1 Blood capillaries of the liver packed with tumor cells ($\times 230$)
 No 2 Neoplastic invasion of a pancreatic lobule ($\times 230$)
 No 3 Edge of a tumor cell nodule in the renal cortex ($\times 230$)
 No 4 Uterine endometrium heavily infiltrated by tumor cells ($\times 230$)

spinal fluid was clear and showed no increase in pressure. The cerebrum was moderately edematous and on the cut surface showed multiple cystic spaces up to one centimeter in diameter. These contained a cloudy yellow fluid. The only green area found in the brain was in the choroid plexus of the left lateral ventricle.

The pituitary was replaced by a mass of green tumor tissue which measured 2.4 by 2.3 by 1.3 centimeters. The sphenoidal sinus and posterior ethmoidal air cells were filled with the tumor tissue. Both orbital cavities were invaded in the retro-orbital recesses by tumor tissue with partial destruction of the supra-orbital plates. The retropharyngeal canal was patent and a probe could be readily passed from the much enlarged sella to the pharyngeal mucosa.

On microscopic examination the tumor tissue was found to have a very wide distribution corresponding to the green and maroon areas described grossly. The tumor cell was a round or oval cell averaging from nine to twelve microns in diameter in the section. The nucleus was placed acentrically at the edge of the cell and showed a rather lightly staining chromatin material without radial distribution of the granules. The cytoplasm was quite plentiful and was clear. No eosinophilic or basophilic granules were present. The cells were constant in their appearance in all tissues. Eosinophilic and neutrophilic polynuclear cells were quite numerous. There were many pigment laden phagocytes present, especially in sections from the nodules which grossly had shown a green color. This pigment was phagocytized blood from obstructed capillaries and varied from recognizable red blood cells through amorphous masses to crystalline deposits.

The various tissues retained in part their specific structures but showed a diffuse or massive infiltration of tumor cells. The lymph nodes and spleen were extensively infiltrated by tumor cells but the lymph follicles persisted to some extent. The liver cells were atrophic due to the tumor cell invasion and anoxemia. The blood vessels throughout the body were filled with tumor cells indicating that a marked leukemia was present at the time of death.

The vacuoles found grossly in the brain showed few tumor cells about them and represented a simple liquefaction process. This necrosis was produced by the obstruction of many of the arterioles by tumor cells with resultant small localized anemic infarctions of the cerebral substance. The pituitary was almost completely destroyed by tumor tissue and it was only with difficulty that any trace of its original structure could be found. The pancreas in addition to small masses of tumor cells showed areas of endothelial phagocytes having a foamy appearance.

Autopsy summary. A chloroma was found involving the periosteum of the skull, ribs, sternum, and vertebral bodies (the long bones were not examined), the thoracic and abdominal lymphoid tissue, the thymus, lungs, pericardial sac, liver, spleen, pancreas, kidneys, dura, pituitary and choroid plexus of the left lateral ventricle. The tumor was in a leukemic phase with all the vessels showing an abundance of the tumor cells. There was marked anemia and a generalized edema with pitting of the ankles and feet, a fatty degeneration of the liver and kidneys, calcification of the costal cartilages with abnormal softening of the bone of the ribs, sternum, vertebral bodies, and to a lesser extent of the skull cap. The cerebral arterioles were thrombosed by tumor cells with multiple areas of liquefaction necrosis. The thyroid gland and adrenals were hypoplastic. There was a terminal bronchial pneumonia.

DISCUSSION

Nine days before death the patient had a white blood count of 10,100 white blood cells with no recognizable cancer cells in the blood stream. At autopsy there was a marked leukemia, sufficient to cause thrombosis of the cerebral vessels. The examination of the eyes three days before death showed definite evidence of leukemia with thrombosis of the arterioles.

The complete destruction of the pituitary might well have been related to the calcium deficiency in the bones and increase in the cartilages. No roentgen-ray evidence of such a change was noted during the examination eight days before death.

Fixed sections of the tumor stained with Weigert's iron hematoxylin and eosin, Goodpasture's oxidase stain and Wright's stain were examined by Dr Raphael Isaacs of the Simpson Memorial Institute at Ann Arbor and Dr Carl V. Weller of the University of Michigan. Dr Isaacs concluded that the tumor cell, which in no case showed oxidase granules, was of the lymphocytic series rather than of the myelocytic series, but might possibly be of the plasma cell type. Dr Weller felt that no classification of the cell as to lymphocytic or myelocytic origin was justifiable and that the tumor cell was too primitive to indicate the potentialities of differentiation of its parent type.

The extensive deposits of blood pigment in various stages of phagocytization in the tumor nodules were responsible for the green discoloration of tissue which characterized the so-called chloroma. There was no evidence in our case that the tumor cells themselves had any relationship to the green pigmentation. There may have been a faulty production of hemoglobin or an increased destruction—which, we are not prepared to say—but the green color was due to phagocytosis of the red blood cells in the capillaries in the tumor nodules. Tumor nodules may uncommonly occur without any green color, and in the leukemic invasion of the organs there is no green pigmentation.

It is to be noted that the tumor affecting bone appeared upon only one side in every case, that side being the one where the nutrient vessels entered the bone.

SUMMARY

A case is reported of chloroma in a 13 year old white female. The tumor was in an aleukemic phase nine days before death but was leukemic at death. There was a very extensive involvement of the cranium and body viscera. The tumor cell did not show the oxidase reaction.

CONCLUSION

- 1 Chloroma is a faulty designation as the green coloration is not specific of any one tumor cell type.
- 2 The green pigmentation is due to phagocytosis of the blood in the obstructed capillaries by the endothelial cells.
- 3 The tumor cell of chloroma is not necessarily myelocytic in origin.

EDITORIAL

THE REPORTED INCREASE IN INSANITY AND FEEBLEMINDEDNESS

It has been frequently stated that an alarming increase is occurring in the numbers of the insane and of the feeble-minded. This assumption has influenced many legislators in favor of optional or compulsory sterilization of the mentally afflicted as a means of limiting this increase. In May of 1934 the American Neurological Society appointed a committee to study the whole question of eugenical sterilization. This committee, working under a grant from the Carnegie Foundation, brought in its preliminary report in 1935. The full report has only recently been available in published form.¹ It contains a very interesting review of the data bearing upon this matter of the increasing frequency of insanity and feeble-mindedness.

In previous studies great stress has been laid upon the rapid rise in the number of insane per 100,000 of population as indicating a great increase in mental disease. There exists, however, no adequate survey of the entire population and the rates quoted are based for the most part upon the number of hospitalized insane in the community. This number, however, can not be taken as a true index of the incidence of mental disease since it is very obviously influenced by the growing recognition on the part of the public of the desirability of commitment, by prevailing economic situations which may render commitment as opposed to the expense of home care more imperative, and by the availability of adequately equipped hospitals which diminishes the family resistance to institutional care for one of its members. The number of hospitalized insane no doubt bears some relation, modified by the above factors, to the total of living cases in the population, but a much less definite relation to fluctuations in incidence. A study of various states shows that where the level of public education is high and where well-managed psychopathic institutions are provided the commitment rate is high whereas in states with a lower level of literacy and with few and poorly equipped mental hospitals the commitment rate is low.

It has been argued that the stress and strain of city life are potent factors in producing insanity, and the higher percentage of urban cases confined in institutions has been cited in support of this view. The explanation however, may be that the residents of cities are better informed as to the value of psychiatric care, that the necessary institutions are usually nearer at hand and that the home care of the insane is less feasible in crowded city living quarters than on farms.

¹ Eugenical Sterilization, Committee of the American Neurological Association for the Investigation of Eugenical Sterilization. New York, The Macmillan Company, 1936, page 211.

The committee made a special study of two relatively stable communities, the states of New York and Massachusetts, to see whether new data representing more accurately the fluctuations in true incidence of mental disease could be obtained. In both of these states there has been a well publicized campaign for mental hygiene for some years, and both are well provided with strategically placed mental hospitals. It was felt that a study of the admission rate (first admissions), as opposed to the number of inmates of hospitals, in these two states over a period of years might throw new light on the subject.

In the interpretation of the data the estimated increase in the population has been taken into account as well as the fact that the average age of the population is increasing. Also the age periods at which the various psychoses occur has been allowed for. Since paresis, for example, rarely occurs in those under thirty-five, the admission rate of paretics was calculated in relation to the quota of the population thirty-five or over. The lower age limit for manic depressive psychosis and for dementia precox was taken as fifteen, that for cerebral arteriosclerotic and senile dementias as fifty-five, and that for all psychoses combined as fifteen years. In Massachusetts the period studied was from 1920 to 1933, both inclusive, and in New York the years 1917 to 1934, both inclusive, were reviewed.

In Massachusetts the admission rate for all psychoses combined was 102.0 per 100,000 in 1920. In the ensuing years it fell as low as 94.0 and rose as high as 118.0 but for the last three years of the period studied the figures were 100.0, 98.5 and 102.0. Similar figures for all psychoses in the state of New York were 94.9 in 1917 and for the last three years of the period 106.0, 110.0 and 111.0. It is apparent that there has been at least no alarming increase in the admission rate for mental disease in these two large and relatively stable communities in the period investigated.

The analysis of the various groups of mental disorders as to their admission rates revealed some interesting facts. The combined group of manic depressive psychosis and dementia precox showed no significant change in admission rate during the period involved. The alcoholic psychoses in New York State showed a marked drop in admission rate during the first few years before and after prohibition was instituted, but thereafter the rate rose gradually to preprohibition levels. The admission rate of paretics showed a definite fall in both states. In New York State there was a definite and probably significant increase in the admission rate for cerebral arteriosclerotic and senile dementias.

The investigations of Winston² have shown that admission rates to mental hospitals, corrected for age, have shown no tendency to rise in recent years in England, Wales, Scotland, Australia, New Zealand or the Scandinavian countries. A definite increase was noted only in Germany.

² WINSTON, ELLFN. The assumed increase of mental disease, *American Journal of Sociology*, 1935, 41, No. 4.

Such data are of course not conclusive proof that insanity and feeble-mindedness are not increasing. Nothing but repeated surveys of the total population could be considered final. However the results of these studies are much stronger evidence against any great increase than has heretofore been put forward as indicating it.

The conclusion of the committee of the American Neurological Society on this point is of interest. "We do not believe that society needs to hurry into a program based on fear and propaganda. Although the problem of mental disease and defectives is enormous, there exists no new social or biological emergency."

REVIEWS

Modern Treatment and Formulary By EDWARD A. MULLEN, P.D., M.D., F.A.C.S., Assistant Professor of Pharmacology and Physiology, Philadelphia College of Pharmacy and Science, Lieutenant Commander Medical Corps, U.S. Naval Reserve. 707 pages, 20 × 12 cm. F.A. Davis Company, Philadelphia. 1936. Price, \$5.00.

This concise treatise on treatment is designed to be of ready use to the practitioner in his daily office and bedside work. The major portion of the volume is devoted to the materials of pharmacotherapy. The presentation of the physician's drug armamentarium is set forth in more than two thousand suggested prescriptions. The latest Pharmacopoeial nomenclature is employed. The arrangement of the *materia medica* is under the names of the diseases, cross references are frequent.

The appendix of the book considers many subjects in resume form of special interest to the physician. Among these subjects are formulae for fluid foods, diet tables, intravenous technic, dose tables and the antidotal treatment of various poisons.

The reviewer regrets that the table of antidotes is fragmentary. Doses of antidotes and specific information are not frequently included. The established nitrite-thiosulfate treatment of cyanide poisoning is omitted, most unfortunately the sodium formaldehydesulfoxylate treatment for bichloride of mercury poisoning has not been included and the treatment for barbiturate poisoning is naive and insufficient.

In the light of modern pharmacological opinion, i.e., writing a prescription based on the known action of one dependable drug, many of the prescriptions included seem archaic and bear the markings of the age of polypharmacy. Thus in one prescription, page 202, for enuresis the drugs *rhhus glabra*, ergot, belladonna, *triticum* and *jaborandi* are prescribed.

Despite the above criticisms the author is to be congratulated on the compilation in such readily accessible manner of so much useful information pertinent to the daily work of the practitioner.

J. C. K., JR.

A Text-Book of Pharmacology and Therapeutics or the Action of Drugs in Health and Disease By ARTHUR CUSHNY, M.A., M.D., LL.D., F.R.S. Eleventh Edition, thoroughly revised by C. W. EDMUNDS, A.B., M.D., Professor of *Materia Medica* and Therapeutics and Director of the Pharmacological Laboratories, University of Michigan, and J. A. GUNN, M.A., M.D., D.Sc., F.R.C.P., Professor of Pharmacology and Director of the Nuffield Institute for Medical Research, University of Oxford, England. 808 pages, 23 × 15 cm. Lea and Febiger, Philadelphia. 1936. Price, \$6.50.

Pharmacologists welcome again the revision of this widely used treatise on the action of drugs. Eleven revisions bespeak its usefulness in the fields of pharmacology and medicine. Although three years only have passed since the appearance of the last revision of this text, the rapid strides in the field of medication embraced by the new volume make its appearance timely.

The book is divided into an introduction and seven parts. Part I includes the action of inorganic substances, Part II embraces substances which are characterized chiefly by their local action, in Part III, the action of drugs after absorption is discussed, Part IV treats of anthelmintics, Part V is devoted to antiseptics and disinfectants, Part VI is concerned mainly with *Chaulmoogra* oil and the subjects of Part VII are vaccines, toxins and antitoxins.

With certain slight alterations the arrangement of the contents has not been changed greatly. Simpler substances, e.g. salts, have been placed nearer the front of the treatise and groups of drugs have been collected into larger classes.

Many of the subjects which were missing in the last edition are to be found in the present revision. Among these is a short resume of the action of drugs on cells, an extension of the sections on liver therapy, arsphenamine, avertin, atabrine and carbarsone.

The modern treatment of cyanide and mercuric chloride poisoning is included, though the mechanism of the action of the latter is not mentioned. The statement on page 428 that picrotoxin has not been employed in therapeutics in cases of collapse is questionable.

The style of the book is concise and lucid and its general printing, arrangement, excepting many of the structural formulas, is excellent.

The reviewer is of the opinion that this revision, like those in the past will continue to rank high among the textbooks in the English language.

J C K, JR

Chronic Indigestion By C J TIDMARSH, M A, M D, F R C P (C) 143 pages
14 X 20 cm Longmans, Green and Company, New York 1936 Price, \$1 50

The author's purpose in writing the book apparently seems to be threefold. He desires to educate the patient, to supplement the advice of the physician and to stress the need for cooperation between patient and physician. The information given is not intended to allow the patient to treat himself but rather to help him in carrying out instructions intelligently.

The book is written in elementary style and does not go over the heads of its lay audience. The approach through anatomy and physiology to causes, symptoms, diagnosis (investigation of case) and treatment gives the layman the accepted method of understanding disease processes. The limitation of its discussion to the type of indigestion associated with definite pain accounts for the author's ability to keep the size of his book within commendable limits.

It is indeed gratifying to see the emphatic indictment of the use of tobacco as an accessory factor in the production of peptic ulcer. It would seem, however, that other dogmatic statements are out of place in a book of this kind. Reference is made to such remarks as "ulcer pain is never present before breakfast" and "vomiting never occurs in the absence of pain." Moreover, in the discussion of cancer of the stomach the mere mention that "a person over 35 years of age who has not had previous attacks of indigestion and now complains of loss of appetite, etc., should be presumed to have cancer of the stomach until proved otherwise," may be enough to cause hysteria. It would be far more desirable in writing for laymen to suggest that such may be a possibility. The remarks about healing of ulcer are also somewhat misleading. One gets the impression that ulcers heal rather promptly (three to four weeks) whereas in the majority of cases, even under the best of conditions, actual healing is not consummated for months. Patients may as well know this and be resigned to months of cooperation in following out their treatment. The recommendation of sanatoria for ulcer cases is unusual though it may help to impress the patient with the necessity for readjustment of his habits and environment. The stress laid upon complete examination is commendable.

There are other minor criticisms but on the whole the author accomplishes his purpose. The book is concise and proves to be very readable.

S M

Keeping Your Child Normal By BERNARD SACHS, M D 148 pages, 13 5 × 19 cm
Paul B Hoeber, Inc, New York 1936 Price, \$1 50

Out of many years of experience in dealing with the problems of childhood, Dr Sachs has written this little book of mellow wisdom. It is the sort of book that should be read by every physician and layman who has to deal with children—and preferably read in the evening with a leisurely and thoughtful mind. By the same token it will probably be read by very few of the persons most in need of it, because it contains little that is spectacular, and because it offers no new theories to try out on the next little victim who comes along.

Throughout all the pages of his book, Dr Sachs preaches the doctrine of common sense in handling children, and he repeatedly warns against a too eager acceptance of the latest psychological theories of child training. "A little respect for tradition and for the experience of the past is no obstacle to true progress." He shows vividly the harm that may be done to a perfectly normal child by subjecting him, for example, to the influence of a sexually minded psychoanalyst, or the damage done by "modern parents" who subscribe to the doctrine of "complete self-expression" for their youngsters.

Dr Sachs misses very few of the many aspects of child psychology, and there are few that he does not enlighten with a pertinent comment. A multitude of topics such as the responsibility of the father in the guiding of his children, the value of discipline in the very young, the effects of reading and movies, juvenile delinquency, the relative importance of heredity versus environment, the need of inculcating the old-fashioned virtues of consideration, honesty, and industry, the proper conduct of social service agencies and child guidance clinics are all touched on in this book.

The large section of the book, which is devoted to what the author terms "The Use and Abuses of Psychoanalysis," is essentially a biting criticism of psychoanalysis as it is practiced today. This chapter is well worth reading as the opinion of a sane and experienced psychiatrist on this particular subject, but the reviewer cannot see how it contributes very much to the discussion on "Keeping Your Child Normal."

C H

Tuberculosis in the Child and the Adult By FRANCIS MARION POTTENGER, A M, M D, LL D, F A C P 611 pages, 16 × 23 5 cm C V Mosby Company, St Louis 1934 Price, \$8 50

The author's wide experience and uncommonly sane clinical judgment have enabled him to produce a very valuable volume on tuberculosis in the child and in the adult. The modern concepts of the development of primary tuberculosis and of its later course have been fully presented. The subject of the relationships between allergy and resistance in tuberculosis is interestingly discussed. The author feels that allergy plays a large role in combating the infection. The visceral reflexes involved in the symptomatology of pulmonary disease receive full attention. Dr Pottenger has long had a special interest in this subject. He is also among those who attribute considerable therapeutic value to tuberculin. In discussing the diagnostic use of tuberculin more might have been added as to the dangers of the subcutaneous test, and the advantages of the intracutaneous method might have been more strongly set forth. The discussions of the clinical aspects of the disease and of its treatment are excellent. The volume is richly illustrated with roentgenograms. Dr Pottenger's book will be of great value to internists and pediatricians who feel the need of a modern one volume text on tuberculosis.

Dr Walter C Swann (Fellow), Huntington, W Va—1 reprint,
Dr Hyman I Goldstein (Associate), Camden, N J—1 reprint
-

Dr Charles H Cocke (Fellow), Asheville, N C, was the orator for the annual meeting of the Jefferson County (Ky) Medical Society, held during December in conjunction with and sponsored by the Louisville Tuberculosis Association

Dr Edgar F Kiser (Fellow), Indianapolis, Ind , has been elected President of the Indianapolis Medical Society

At the annual meeting of the Rensselaer County (N Y) Medical Society, Dr Stephen H Curtis (Fellow), Troy, was elected President for 1937

Dr Harold Swanberg (Fellow), Quincy, Ill , was reelected Secretary-Treasurer of the Mississippi Valley Medical Society at its annual meeting in Quincy, Ill , during

November Dr Dan G Stine (Fellow), Columbia, Mo , was elected to the Board of Directors for a two-year term for Missouri

The Medical Association of Puerto Rico held its annual meeting in Santurce, P R, December 18-20 Dr O Costa Mandry (Fellow) was President of the Committee on Arrangements A paper on "Applied Therapeutics" by Dr A C Morgan (Fellow), Philadelphia, was read by invitation Other members contributing to the program were Dr Ramon M Suarez (Fellow), "Comparative Effects of Crude and Purified Liver Extracts in the Anemia of Sprue Administered Intramuscularly and Intrasternally", Dr Enrique Koppisch (Associate), "Tissue Reactions in Diseases Caused by Filterable Viruses", and Dr Rafael Rodriguez Molina (Fellow), "Hematological Studies on Malaria in Puerto Rico"

Major General M W Ireland (Fellow) is President of the National Board of Medical Examiners of the United States Among Fellows of the College who are members of this Board are Dr Walter L Bierring, Des Moines, Dr Charles A Elliott, Chicago, Dr Reginald Fitz, Boston, Dr Waller S Leathers, Nashville, Tenn, Dr George W McCoy, U S Public Health Service, Dr William deB MacNider, Chapel Hill, N C, Dr Walter W Palmer, New York City, Dr Thomas Parran, Surgeon General, U S Public Health Service, Dr O H Perry Pepper, Philadelphia, Dr Charles R Reynolds, Surgeon General, U S Army, Dr P S Rossiter, Surgeon General, U S Navy, Dr Harold Rypins, Albany, N Y, Dr J F Siler (M C), U S Army, Dr J Gurney Taylor, Milwaukee, Wis

Dr Wilmar M Allen (Fellow) has been appointed Director of the Hartford (Conn) Hospital

Dr Herman M Baker (Fellow), Evansville, Ind, has been made President-Elect of the Indiana State Medical Association for 1937

Dr James B Collip (Fellow), Professor of Biochemistry, McGill University Faculty of Medicine, Montreal, will deliver a lecture on "The Significance of Recent Studies on the Anterior Pituitary and Related Glands," April 16, 1937, this being one of a series of lectures sponsored by the William Harvey Society of Tufts College Medical School, Boston

The third annual symposium at Duke University School of Medicine, Durham, N C, was held during October on diseases of the heart, circulation and kidneys Fellows of the American College of Physicians included among the speakers were Drs Warfield T Longcope and Louis Hamman, Baltimore, Dr Carl J Wiggers, Cleveland, Dr Charles C Wolferth, Philadelphia, Dr Frank N Wilson, Ann Arbor, Dr William deB MacNider, Chapel Hill, Dr James Edwin Wood, Jr, Charlottesville, Va, Dr William B Porter, Richmond, Va, Dr Stewart R Roberts, Atlanta, and Dr Soma Weiss, Boston

Dr Charles E Sears (Fellow), Portland, has been elected a Vice-President of the Oregon State Medical Society

Dr Walter F Donaldson (Fellow), Pittsburgh, has been reelected Secretary of the Medical Society of the State of Pennsylvania

The bulk of an estimated estate of more than \$200,000 has been bequeathed by the late Frances T Kinsey to the University of Pennsylvania to support and develop the Gastro-Intestinal Clinic at the University Hospital, under the direction of Dr Thomas Grier Miller (Fellow), or for such other activities in this field as he may desire

Dr Samuel B Scholz, Jr (Fellow), Philadelphia, has been elected a vice-president of the Association of Life Insurance Medical Directors of America

Dr Henry W F Woltman (Fellow), Rochester, Minn, has been elected President of the Central Neuropsychiatric Association

Dr Edward A Strecker (Fellow), Philadelphia, has been appointed a member of the advisory committee of the Friedsam Foundation, in connection with its program of research in child neurology. The research program will include studies of (1) organic and functional diseases of the nervous system in children, (2) neuroses and psychoses in early life, and, (3) social personality and home problems. The program will be carried on through grants and scholarships to research workers throughout the world. Only original work that promises to be fruitful of results will be considered. The applicant must state specifically the problem under investigation and the methods to be pursued. The Council of the Foundation will publish the results from year to year.

Dr Herbert L Bryans (Fellow), Pensacola, Fla, has been elected a Vice-President of the Gulf Coast Clinical Society

Dr Gordon B Myers (Associate), Detroit, has been appointed Professor and acting head of the Department of Medicine of Wayne University College of Medicine. Dr Hugo A Freund (Fellow), Detroit, has been appointed Professor of Clinical Medicine

Dr Eugene M Landis (Fellow), Philadelphia, gave the second Harvey Society Lecture at the New York Academy of Medicine, November 19, on "The Passage of Fluid Through the Capillary Wall"

Dr George R Minot (Fellow), Professor of Medicine, Harvard University Medical School, Boston, delivered the sixth Walter M Brickner Lecture at the Hospital for Joint Diseases, New York City, November 19, on "Anemia Etiology, Diagnosis and Treatment"

Dr Soma Weiss (Fellow), Boston, was guest speaker at the joint meeting of the Cincinnati Academy of Medicine and the Heart Council of Greater Cincinnati,

recently, his subject being "The Relation of the Cardiovascular System to the Nervous System"

As a memorial to the late Dr James M Anders (Master), Philadelphia, the Philadelphia County Medical Society devoted its meeting of November 25 to the observance of the annual Pennsylvania Health Day, a movement primarily sponsored in its beginning by Dr Anders Dr George E Pfahler (Fellow), Philadelphia, delivered a tribute to Dr Anders, and Dr Baldwin L Keyes (Associate), Philadelphia, presented a report of the Society's noise abatement committee, whose work was one of the last activities sponsored by Dr Anders before his death last August

Dr Elliott P Joslin (Fellow), Boston, is President of the Interstate Post-Graduate Medical Association

Dr Byrl R Kirklin (Fellow), Rochester, Minn, is President-Elect of the American Roentgen-Ray Society Dr Charles A Waters (Fellow), Baltimore, now occupies the Presidency

Dr John H Wyckoff (Fellow), New York City, recently assisted in the presentation of a symposium on sterilization before the section of obstetrics and gynecology of the New York Academy of Medicine

Dr Ray M Balyeat (Fellow), Oklahoma City, and Dr Hal M Davison (Fellow), Atlanta, were guest speakers on the program of a clinical congress held during the past autumn by the Chattanooga and Hamilton County (Tennessee) Medical Society

In honor of his thirty-three years of service to organized medicine, Dr Rock Sleyster (Fellow and Governor for Wisconsin), Wauwatosa, Wis, was tendered a dinner by the Medical Society of Milwaukee County at the Wisconsin Club, Milwaukee, on November 14 Dr Arthur J Patek (Fellow), Milwaukee, was toast-master Dr J Gurney Taylor (Fellow), Milwaukee, was one of those delivering an address Dr Sleyster is Chairman of the Board of Trustees of the American Medical Association In 1903 he became Secretary of the Calumet County Medical Society, holding the post for six years In 1910 he was elected Assistant Secretary of the State Medical Society of Wisconsin and its Secretary in 1914, holding this appointment until 1923 In 1924 he was elected President of the State Society, and since 1925 he has been its Treasurer From 1918 to 1923 Dr Sleyster was Editor of the Wisconsin Medical Journal He served as delegate to the American Medical Association from 1915 to 1926, and for the last four years of that period he was Vice Speaker of the House of Delegates He has been a Trustee since 1926 and Chairman of the Board since 1935 He graduated from the University of Illinois College of Medicine, Chicago, 1902 At present he is medical director of the Milwaukee Sanitarium

Dr Francis E Harrington (Fellow), Minneapolis, has been reelected Secretary of the International Society of Medical Health Officers

The Alumni Association of the College of Medical Evangelists, Los Angeles, held its third annual postgraduate assembly in Los Angeles, December 6. Among the speakers were Dr James F Churchill (Fellow and Governor for Southern California), San Diego, "A Discussion of Cardiac Drugs and Their Uses", Dr Alvin G Foord (Fellow), Associate Professor of Pathology, University of Southern California School of Medicine, "Laboratory Diagnosis for the General Practitioner", and Dr William J Kerr (Fellow and Regent), Professor of Medicine, University of California Medical School, "Obesity and Its Complications".

Dr William B Castle (Fellow), Boston, addressed the graduate teaching clinic of the Central Maine General Hospital, Lewiston, Maine, December 18, on "Development of the Knowledge of Vitamin Deficiency Diseases".

Dr Bernard Fantus (Fellow), Chicago, was a guest speaker on the program of the joint meeting of the Wayne County Medical Society and the Detroit Retail Druggists Association, December 7, when the newly revised Pharmacopoeia and the National Formulary were discussed.

Dr William M Donald (Fellow), Professor and Head of the Department of Medicine, Wayne University College of Medicine, Detroit, was a guest of honor at a joint meeting of the staff of the Receiving Hospital and the medical faculty recently, in recognition of his many years of service to both institutions. Dr Donald is seventy-six years of age and has been a member of the teaching staff of his alma mater since 1889. He was President of the Wayne County Medical Society in 1922 and has been a Fellow of the American College of Physicians since 1917.

Dr Sydney R Miller (Fellow and Regent), Baltimore, and Dr Leander A Riely (Fellow and Governor for Oklahoma), Oklahoma City, have been elected Vice-Presidents of the Southern Medical Association.

Dr Henry A Luce (Fellow), Detroit, was one of the speakers on a panel discussion of the relation of social security to the practice of medicine, sponsored by the medical economics committee of the Wayne County Medical Society and the Michigan State Medical Society, December 9.

Dr James H Black (Fellow) has been promoted to Professor of Clinical Medicine (Allergy) on the Faculty of Baylor University School of Medicine, Dallas.

Dr George R Minot (Fellow), Boston, on December 1 at the Waldorf-Astoria Hotel, New York City, received the annual award for research in the field of nutrition leading to the prevention of disease and the advancement of health, the award being made by the Associated Grocery Manufacturers Association of America.

Dr Hugh S Cumming (Fellow), formerly Surgeon General of the U S Public Health Service, was Chairman of the local Committee on Arrangements for the

second National Conference on College Hygiene, held in Washington December 28 to 31

Dr Cumming was presented with the Marcellus Hartley Gold Medal "for eminence in the application of science to the public welfare" at the annual meeting of the National Academy of Sciences, in Chicago during November

Dr Earl B McKinley (Fellow), Dean and Professor of Bacteriology, George Washington University School of Medicine, is on sabbatical leave, dating January 1, for a trip to the Orient, where he will conduct research on leprosy under the auspices of the American Leprosy Foundation, formerly the Leonard Wood Memorial. Dr McKinley will later continue his travels around the world, gathering material concerning the geographic distribution of disease for inclusion in a new book now in preparation, "A Cartography of Disease"

Dr Charles Franklin Craig (Fellow), Professor of Tropical Medicine, Tulane University of Louisiana School of Medicine, New Orleans, delivered the annual oration of the Smith-Reed-Russell Society, George Washington University School of Medicine, Washington, D C, on "Factors Influencing the Transmission of Malaria," during November

Dr James S McLester (Fellow and ex-Regent), Birmingham, Ala, has been appointed Professor of Medicine at the University of Alabama School of Medicine. Dr Edgar Gilmore Givhan, Jr (Associate) and Dr James B McLester (Associate) have been appointed Associate Clinical Professors of Medicine

Dr Thomas B Magath (Fellow), Rochester, Minn, has retired as Editor of the "American Journal of Clinical Pathology," after serving six years. Dr Robert A Kilduffe of Atlantic City, N J, succeeds Dr Magath as Editor

Dr Charles A Doan (Fellow), Professor of Medicine and Medical Research, Ohio State University College of Medicine, has been appointed Chairman of the Department. Dr George T Harding, III (Fellow), is Assistant Clinical Professor of Medicine (Psychiatry), and Lt Col Frank H Dixon (Fellow), Medical Corps, U S Army, is Professor of Military Science

Dr Lee Rice (Fellow), San Antonio, Tex, is President of the Texas Club of Internal Medicine

Dr Porter P Vinson (Fellow), Rochester, Minn, has been appointed Professor and Head of the Department of Bronchoscopy, Esophagoscopy and Gastroscopy at the Medical College of Virginia, Richmond. He will also be in charge of chronic pulmonary diseases at the Memorial Hospital

Dr David P Barr (Fellow and Regent), St Louis, has been elected President of the Central Society for Clinical Research

Dr Charles H McEnerney (Fellow), Washington, D C, has been reelected Secretary of the American Society for the Study of Arthritis

Dr Leroy S Peters (Fellow), Albuquerque, N M, has been made President-Elect of the southwestern Medical Association Dr Howell S Randolph (Fellow), Phoenix, Ariz, and Dr Orville E Egbert (Fellow), El Paso, Tex, have been elected Vice-President and Secretary respectively

Dr N M Marr (Associate), St Petersburg, Fla, has been elected President of the Pinellas County (Florida) Medical Society

Dr A Clayton McCarty (Fellow), Louisville, Ky, has been elected President of the Jefferson County (Kentucky) Medical Society

Dr George A Gray (Associate), Abilene, Tex, has been appointed Director of the Nolan County Health Unit

Dr R M Wylie (Fellow), Huntington, W Va, has been elected President of the Cabell County (West Virginia) Medical Society

OBITUARIES

OSKAR KLOTZ, M B , M D , F R C P (C) , F A C P , F R S C ,
1878-1936

THOSE who knew Oskar Klotz well find it difficult to express to others their full appreciation of the man. Widely known as a research worker and teacher, studying, investigating, directing and advising, with his activities spread over three continents, he became an authority in many of the departments of his chosen field of pathology. To his associates he was a great source of inspiration. With a remarkable ability to apply his knowledge whether from his own or other source, he was peculiarly fitted for the study of special problems in the origin of disease, its manifestations and its effects. The appended outline of his preparatory and postgraduate education, his various appointments, his memberships and offices held in national and international societies bespeak his wide variety of interests, the recognition by his fellow workers of his ability and genius and the high esteem in which he was held by men with whom he came in contact in his many spheres of activity.

Many tributes have been paid to him and to his work perhaps none more speaking than that from the Sisters of Mercy in Pittsburgh, who learning of his death sent the message that they could never forget the aid he gave them in the development of their hospital. Night after night was given freely to them during his busy life in that city, after days of labor in the University and its laboratories.

His contributions to medical literature number over one hundred titles. His studies of disease of the circulatory system made him an international authority. In tropical diseases he became one of the leaders. In his University he developed departments which proved him a great administrator. His library contained all that was important of the new and the most valuable of the old. His studies, his writings, his reading gave evidence that he appreciated the historical approach to questions under investigation. His grasp of any subject was wide, his early death means the loss of many important contributions to historical medicine.

His papers based on such reading were written in faultless English, and in such a style as to make him one of our outstanding essayists. I have frequently found myself looking upon him with Welch and Warthin as the three admirable, lovable pathologists of our time.

He was born in Ontario of Danish stock from Kiel, Holstein. His father was Chief Astronomer of the Dominion Observatories, a graduate of the University of Toronto and of Michigan, whose achievements won world wide fame. Two brothers, one of whom pre-deceased him, also graduated in medicine at the University of Toronto.

The funeral on November 15 was from Osler Hall of the Academy of Medicine, Toronto, where he presided last year. The service was conducted by Dr H J Cody, President of his University, and by Sir Robert Falconer, President Emeritus, in the presence of the Lieutenant Governor of the Province, representatives of the National Research Council at Ottawa, his colleagues in Pittsburgh and The University of Toronto, most of the Fellows of the Academy, and many of his students and friends.

To his wife, Stella M Scovill, who survives him, this College extends its sincerest sympathy.

Oskar Klotz, M B, M D, C M Born, January 21, 1878, at Preston, Ont. Attended Ottawa Collegiate Institute and the University of Toronto (M B, 1902), M D, C M, Faculty of Medicine McGill University, 1906. Postgraduate study at the University of Bonn, Bonn, Germany, 1905, University of Prague, Prague, Bohemia, 1905, University of Freiburg, Freiburg, Germany, 1908, University of Marburg, Marburg, Germany, 1914, house physician, Ottawa General Hospital, 1902-03. Governor's Fellow in Pathology, McGill University, 1903-05, Fellow in Pathology, Rockefeller Institute 1905-06, demonstrator in Pathology and Bacteriology, McGill University, 1905-07, assistant pathologist, Royal Victoria Hospital, 1905-10, pathologist, Maternity and Alexandra Hospitals, Montreal, 1905-10, lecturer in Pathology, McGill University, 1907-10, professor of Pathology and Bacteriology, University of Pittsburgh, 1910-20, director, Magee Pathology Laboratory, Pittsburgh, 1910-20, professor of Pathology, Faculdade de Medicina, Sao Paulo, Brazil, 1920-23, professor of Pathology and Bacteriology, University of Toronto, 1923 to date, director of pathology laboratories, Toronto General Hospital, 1923 to date, consulting pathologist, Hospital for Sick Children, 1923 to date, at one time a special member, Yellow Fever Commission, Rockefeller Foundation, member, Zeta Psi, Nu Sigma Nu and Alpha Omega Alpha Fraternities, past president of American Association of Pathologists and Bacteriologists, International Association of Medical Museums, Academy of Medicine of Toronto and Society for Experimental Pathology, member of council of National Research Council of Canada, American Association of the History of Medicine, Ontario Branch of St John's Ambulance Association and the Royal Canadian Institute of Toronto, member, Toronto Health League, Ontario Medical Association, Canadian Medical Association, Royal Society of Canada, Royal College of Physicians and Surgeons of Canada, Cancer Commission and chairman of subcommittee on Cancer Research (Ontario), International Association of Geographical Pathology (joint chairman for Canada), International Society for the History of Medicine, Medical Advisory Committee in conjunction with Ontario Crippled Children, Pathological Society of Great Britain and Ireland, Society for Experimental Biology and Medicine, Society for Tropical Diseases, American Society of Parasitologists, American Society of Tropical Medicine, Association of American Physicians and the American College of Physicians (Fellow, 1924).

JABEZ H ELLIOTT, M B, F A C P,
Governor for Ontario

DR WILLIAMS McKIM MARRIOTT

Dr Williams McKim Marriott, Fellow, died in San Francisco, November 11, 1936. He had only recently come to San Francisco from Washington University Medical School to assume the duties of Professor of Research Medicine and Dean of the Medical Faculty of the University of California.

Dr Marriott was born in Baltimore, Md, March 5, 1885. He received his B S degree from the University of North Carolina, 1904, and the degree of M D from Cornell University in 1910. He served as Assistant in Biochemistry in Cornell University from 1904 to 1907 and Instructor in Biological Chemistry, Washington University, 1910 to 1914. In 1914 he went to the Johns Hopkins Medical School as Instructor and Associate in Pediatrics, remaining until 1917, when he returned to Washington University, St Louis, as Professor of Pediatrics, which position he held until July 1936, when he came to San Francisco. From 1923 until his resignation in 1936, he was Dean of the Medical Faculty of Washington University. As Professor of Pediatrics he became Pediatrician in Chief, Barnes Hospital, St Louis Maternity Hospital and Washington University Clinics. He also held the title of Physician in Chief of St Louis Children's Hospital.

During his academic career he was honored by the following lectureships: In 1920, Harvey Society Lecturer, New York, 1921, Packard Lecturer, Philadelphia, 1925, Lecturer, Chicago Institute of Medicine, 1927, Annual Lecturer, San Diego Academy of Medicine, 1932, Visiting Lecturer, University of California Medical School, and Lecturer, California Academy of Medicine, San Francisco.

The following list of society memberships and offices indicates the breadth of his medical interests as well as the recognition which his position in the profession merited: Fellow of the American College of Physicians, Regent from 1926 to 1929, Vice-President, 1929 to 1930. Fellow of the American Medical Association, member of the Council on Pharmacy and Chemistry and member of Foods Committee. Member of the Council American Pediatric Society. President of the St Louis Pediatric Society. Member of Council American Society of Clinical Investigation. Association of American Physicians, American Society of Biological Chemists, American Association for the Advancement of Science, Society of Experimental Biology and Medicine, Harvey Society of New York (Honorary Member), American Academy of Pediatrics, Southern Medical Association, Chairman of the Sections on Medical Education and on Pediatrics.

He was a member of the Phi Beta Kappa and Alpha Omega Alpha honorary societies and served on the Editorial Boards of the *American Journal of Diseases of Children*, *American Heart Journal* and the *Journal of Clinical Investigation*.

Dr Marriott's contributions to medical and biological chemical literature were prolific and could not very well be mentioned here, including, as they do, two books, one concerning the relationship of biological chemistry to medical practice, and one on Infant Nutrition. Sections dealing with Pediatrics, in four books and over 80 contributions in the form of articles on biological chemistry and pediatrics.

With this remarkable background, an outstanding figure in American Medicine, Dr Marriott came to California to devote his time and energy

to research medicine and to the Deanship of the University of California Medical School. Before he was well settled in his new environment, his health became impaired by a chronic appendiceal abscess, which was treated surgically, but a blood stream infection ensued, eventually causing his death.

In Dr Marriott's death the American College of Physicians has lost one of its distinguished and loyal members. We in California have lost a warm friend and fellow worker, whose life with us was all too brief.

ERNEST H. FALCONER,
Governor for Northern California

DR WILLIS FASTNACHT MANGES

Willis Fastnacht Manges, M D, D Sc, was born in Luthersburg, Clearfield County, Pa, on December 4, 1876, and died in the Jefferson Medical College Hospital, Philadelphia, on November 24, 1936, of coronary thrombosis after a mercifully brief illness.

Dr Manges attended Gettysburg College, Gettysburg, Pa, and the Philadelphia College of Pharmacy before entering the Jefferson Medical College from which institution he received his M D degree in 1903.

After completing his internship in the hospital of the Jefferson Medical College, Dr Manges became actively associated with the Department of Roentgenology of the same College and Hospital, and in this Department he spent the greater part of his professional life in helpful, progressive work, research, study and in teaching.

Dr Manges entered the field of Roentgenology in the pioneer period of that branch of medical science and lived to become one of its foremost authorities. Dr Manges was fortunate, early in his professional career, to be intimately associated with such masters of medical science as W W Keen, J Chalmers Da Costa, George E de Schweinitz, Chevalier Jackson, Thomas McCrae and other like minded men of medicine who possessed, in addition to their medical knowledge, inspiring and stimulating personalities and who were never content with superficialities, but who sought and encouraged others to seek ultimate truth.

When the World War came, Dr Manges felt it to be his duty to abandon a lucrative and interesting practice, an assured professional and social position and, far more important and difficult for him, to leave his young wife and baby for the uncertainties and vicissitudes of army medical life. Dr Manges established, for the medical department of the Army, an efficient training school for roentgenologists at Camp Greenleaf, Fort Oglethorpe, Ga, that commanded the respect and admiration of the medical world. Many medical officers assigned for duty in the school for roentgenologists received from Dr Manges not only excellent technical training but inspiration for making roentgenology a life work.

After the war the intimate association of Dr Manges with Dr Chevalier Jackson's epoch making studies of the abnormalities and disorders of the air

passages brought about Dr Manges' outstanding contribution in this field, namely, a practical method of detecting the presence of non-opaque foreign bodies in the lower air passages

In 1928 Dr Manges was made Professor of Roentgenology at the Jefferson Medical College in well deserved recognition of the years of altruistic service rendered the medical school in giving inspiring instruction to both undergraduate and graduate students

Dr Manges was elected to Fellowship in the American College of Physicians in 1930 for, unlike many specialists in medicine, Dr Manges was a skilled and understanding physician. His specialty was roentgenology and he limited his actual practice to this field of endeavor but, fortunately for his patients, for his colleagues and for his students, Dr Manges held an active interest in clinical medicine and its problems. Modest to the degree of self effacement, Dr Manges was time and again advanced by the unanimous vote of his professional colleagues to positions of honor in the profession

He was President of the Philadelphia Roentgen Ray Society as well as Secretary, and, later, President of the American Roentgenological Society, and was active and interested in every association that he felt was helpful for the common good of the medical profession

Willis Manges possessed, by virtue of fortunate heredity and entirely natural characteristics, an unusually attractive, admirable and lovable nature. He was unselfish, generous, and interested in helping others. Charitable to the faults and weaknesses of others, he maintained the highest standards of living and thinking in his own life, and commanded the respect and admiration of all who came in contact with him or with his work

Dr Manges is survived by his widow, who was Marie Elizabeth Bosley of Baltimore, and two sons, Willis E and William Bosley. The College has lost a loyal, altruistic and helpful Fellow, the world, a kind, skilled and considerate physician, but no mere words can begin to express what the passing of Dr Manges means to those near and dear to him. One can, however, be thankful that as long as the sons of Dr Manges live, or their descendants, the qualities and characteristics that he so nobly exemplified cannot be lost to the world

E J G BEARDSLEY, M D, F A C P,
Governor for Eastern Pennsylvania

DR MATTHEW A DeLANEY

Brigadier General Matthew A DeLaney (Fellow) of the Army Medical Corps Retired, who served as White House physician during the Taft Administration, died November 1, 1936, at Walter Reed General Hospital, Washington, D C. He had been a patient at that hospital for about two months

From 1931 until his retirement, General DeLaney was one of the As-

sistant Surgeons General His last tour of duty was in command of the Medical Field Service School at Carlisle Barracks, Pennsylvania

Less than a month after the United States entered the World War General DeLaney went to France to command the Pennsylvania Base Hospital No 10 Early in 1918 he was appointed Liaison Officer to the British War Office, London

A native of Waymart, Wayne County, Pennsylvania, where he was born March 6, 1874, General DeLaney was graduated from Pennsylvania Normal School and obtained his medical degree from the University of Pennsylvania in 1898 In 1902 he was graduated from the Army Medical School

General DeLaney had also taken a course at the University of Vienna in 1913-14, and held a Certificate of Public Health from Harvard University Dickinson College, Pennsylvania, last year made him an honorary doctor of science

General DeLaney served in the Philippine Insurrection He was White House Physician from 1909 to 1913 He served on the Mexican Border in 1916 When the World War was ended he became Executive Officer in the Office of the Surgeon General In 1921 he was named Surgeon of the Field Artillery School at Fort Sill, Oklahoma, and in 1927 was ordered to assume the same duties at Camp Devens, Massachusetts The following year he became medical adviser in public health and sanitation, first, to Henry Stimson, and then to Dwight W Davis, who were in turn Governors General of the Philippines In 1931 General DeLaney was ordered to Command Carlisle Barracks, his last station before retirement

In addition to his being a Fellow of the American College of Physicians, he was a member of the American Public Health Association, a Fellow of the American Medical Association and of the American College of Surgeons He contributed many articles to medical journals Military honors accorded General DeLaney include the Distinguished Service Medal from the United States and the Order of St Michael and St George of Great Britain Field Marshal Douglas Haig mentioned him in dispatches for "gallantry on the field" He was a member of the Order of St Lazare of Jerusalem

He belonged to the Metropolitan, Chevy Chase and Army and Navy Clubs of Washington, and the Army and Navy and Polo Clubs of Manila

Surviving General DeLaney is his wife, Mrs Elizabeth V DeLaney, who makes her home in Washington

CAPTAIN OWEN J MINK

Captain Owen J Mink, Medical Corps, U S Navy, the Assistant Chief of the Bureau of Medicine and Surgery, died suddenly at his home at Chevy Chase, Maryland, on October 21 Captain Mink was born at Pectone, Illinois, April 26, 1879, so was 57 years of age at the time of his death He graduated from the Medical School of the University of Michigan in 1903 and was appointed Assistant Surgeon in the Navy June 7, 1904 His

home then was at Wheaton, Illinois. He was promoted Passed Assistant Surgeon June 7, 1907, Surgeon August 29, 1916, Commander July 1, 1918, and Captain, Medical Corps, October 2, 1925.

His first duty was at the Naval Hospital at Philadelphia, following which he received a postgraduate course of instruction in naval medicine at the U S Naval Medical School, completing this postgraduate course in the spring of 1905.

The types of duty performed by Captain Mink were of a most varied character and he held many important posts both afloat and ashore. In 1910 he was a member of the board to study and report upon the causes and prevention of typhoid fever in the Navy and he was a pioneer in the movement to introduce typhoid vaccination in the Navy. After this he served on the U S S West Virginia, then a member of the famous armoured cruiser squadron. During the World War he was on duty at the Naval Training Station, Great Lakes, Illinois. After the war he served as Executive Officer of the U S Naval Hospital, Great Lakes, Illinois, and as Senior Medical Officer in Samoa and later as Senior Medical Officer in the Virgin Islands and Commanding Officer of the Naval Hospital at Saint Thomas. He then served as Commanding Officer of the Naval Hospital at Canacao, P I.

From 1931 to 1933 he was Chief of the Division of Preventive Medicine in the Bureau of Medicine and Surgery. He was appointed Assistant Chief of the Bureau of Medicine and Surgery June 26, 1933.

Captain Mink was an outstanding medical officer of the United States Navy and was particularly distinguished in the fields of bacteriology and preventive medicine. Few men in this country surpassed him in point of knowledge of preventive medicine and public health, particularly in respect to the simple and homely common sense with which he applied this knowledge to the problems of disease prevention. The editor of the Journal of the Royal Army Medical Service quite recently in requesting permission to reprint an article on disease prevention written by Captain Mink, commented on its great value and the many practical features which it contained.

Captain Mink had a most likeable personality. Pleasant, sincere and unaffected, everyone who came in contact with him loved and admired him. He was very fond of flowers and was an ardent amateur gardener. Captain Mink is survived by his wife and three children. His death is a real loss not only to his family and friends but to the Medical Corps and the Naval Service.

P S ROSSITER, M D , F A C P ,
Surgeon General, U S Navy

DR THOMAS CRAIG REDFERN

Dr Thomas Craig Redfern (Fellow), Winston-Salem, N C, was born in Chesterfield County, S C, July 31, 1892. He received his academic training at Clemson College, graduating with the degree of B S in 1912, and receiving his M D in 1916 from the Long Island College Hospital. After serving his internship there, he was for two years assistant surgeon in the United States Medical Corps, followed by a residency in medicine in Barnes Hospital, St Louis.

He became medical director of the City Memorial Hospital, Winston-Salem, N C, in 1920, and Chief of the medical service of that hospital from 1924 to 1931. He was likewise Chief of the Medical Service of the North Carolina Baptist Hospital from 1923 to 1931. From 1924 on, Dr Redfern became an outstanding internist in his community, and besides serving on the staffs of the two hospitals mentioned, was a member of the Governing Board of the Forsyth County Tuberculosis Sanatorium, former President of the Forsyth County Medical Society, and a member of the North Carolina State Medical Society and of the Southern Medical Association, and a Fellow of the American Medical Association, as well as of the American College of Physicians. He was a former member of the Rotary Club and a member of the First Presbyterian Church.

August 15, 1936, he had a coronary thrombosis, succeeded by embolic phenomena, which caused his death from myocardial failure nine weeks later.

Dr Redfern was a leader in his chosen field in his city, always studious, an original thinker, and a man of lovable character. He is survived by his widow and a son and daughter.

CHARLES H COCKE, M D, F A C P,
Governor for North Carolina

DR THOMAS DEWITT GORDON

Thomas Dewitt Gordon (Fellow), of Grand Rapids, Michigan, died November 20, 1936, of coronary disease, aged 56.

Dr Gordon was born in Maxwell, Ontario, on November 1, 1880. Graduating from the University of Michigan Medical School in 1909, he came to Grand Rapids to practice in 1911 directly from the University Hospital where he had been first assistant in Internal Medicine.

Dr Gordon early offered his services to his country in the World War, and with the rank of Captain, organized and took over-seas Ambulance Unit Number 339. Detached over-seas, he became Chief Sanitary Officer of the 85th Division. Returning from the war he again took up his general practice, but soon determined to limit his work entirely to pediatrics in which he was much interested and for which he prepared by postgraduate work both in this country and abroad. In this special work for which he was so well suited, he developed an enviable reputation throughout the state.

Markedly competent and well trained, with a pleasing personality, he was much beloved and appreciated by his patients and his professional brothers. A forceful speaker, with a teacher's ability to handle his subject, he added much to professional discussion and was always in demand for talks on his chosen specialty.

The disease from which he died manifested itself two years earlier and compelled a prolonged absence from his work. He bore his affliction with great philosophy. Some six months before he died he thought himself sufficiently recovered to take a few months postgraduate work and return to practice. Within a few weeks of his return he was again going at full tilt, as was his custom, but the demands of practice soon resulted in a return of symptoms.

Dr. Gordon was an active member of the Blodgett Hospital Staff, an ex-president of the Kent County Medical Society, and a member of various pediatric societies. He had been a member of the American College of Physicians since 1919. Lovable, conscientious, always dependable, the profession has lost a valued member, a wise councillor and friend.

BURTON R. CORBUS, M.D., F.A.C.P.,
Grand Rapids, Mich.

DR. ARTHUR STERN

Dr. Arthur Stern (Fellow), Elizabeth, N. J., died suddenly November 28, 1936, of coronary thrombosis, aged, 68 years.

Dr. Stern was born in Geseke, Westphalia, Germany, in 1868. He received both his preliminary and medical education in his native Germany, but did not practice medicine there. After graduating from the Friedrich-Wilhelms University, and after passing his State Board examination at Munich, he joined the Hamburg-American Steamship Line as ship surgeon, and made five trips in that capacity across the Atlantic. In 1892, he came to Elizabeth, N. J., and began the practice of medicine and surgery. His fame grew sufficiently to justify his specializing in Pediatrics, which he pursued until his death. At the time of his death he held many responsible hospital positions. He was Senior Attending Physician at the Elizabeth General Hospital and Senior Attending Pediatrician at the St. Elizabeth Hospital, both of Elizabeth, N. J.

Dr. Stern became a Fellow of the College on January 30, 1920. He had been a president of the Union County Medical Society and a vice-president of the New Jersey Pediatric Society. He was a Fellow of the New York Academy of Medicine, the American Medical Association and a member of the American Child Hygiene Association. He had published numerous articles.

In Dr. Stern's death, the people of Elizabeth, the profession and the College, have suffered an irreparable loss.

CLARENCE L. ANDREWS, M.D., F.A.C.P.,
Governor for New Jersey

DR JACOB C ATWELL

Following an illness of but two days, Dr Jacob Clinton Atwell (Fellow) of Butler, Pennsylvania, died on November 2, 1936, of pneumonia

Dr Atwell was born in Boyers, Butler County, March 25, 1874. He received his early education in the local public schools and later attended the Slippery Rock State Normal School and the West Sunbury Academy. In 1898 he graduated from the Medico Chirurgical College in Philadelphia, and immediately after established his office in Butler where he became one of the most prominent physicians in the county and where he practiced until the time of his death.

Dr Atwell was a member of the First United Presbyterian Church and took an active interest in the affairs of the church, having been a member of the United Presbyterian Sessions since 1912.

He was an Associate Member of the Pittsburgh Academy of Medicine, a member of the Butler County Medical Society, the Pennsylvania State Society, a Fellow of the American Medical Association, and has been a Fellow of the American College of Physicians since 1912.

During the World War, Dr Atwell was First Lieutenant in the Medical Corps of the U S Army.

Surviving are his widow, Mrs Mollie Jennings Atwell, a daughter, Mrs Charles Midberry of Butler, a son, Jennings Clinton Atwell, Jr, of Butler, and several brothers and sisters.

E BOSWORTH MCCREADY, M D , F A C P ,
Governor for Western Pennsylvania

TUBERCULOSIS OF THE PERICARDIUM, A STUDY OF TWENTY CASES

By CHESTER S. KEEFER, M.D., F.A.C.P., *Boston, Massachusetts*

TUBERCULOSIS of the pericardium is the least common and most serious tuberculous infection of the serous membranes. Generally speaking, it is infrequent, and since it has various clinical features which may not direct one's immediate attention to the pericardium, I am reviewing a series of 20 cases which were observed over a period of several years. The details of the cases are indicated in table 1.

ANALYSIS OF CASES

Age It is agreed that tuberculosis of the pleurae and peritoneum is most often seen between the ages of 15 and 40 years. Everyone who has studied tuberculosis of the pericardium remarks that it is found most frequently over 40 years of age.^{1, 2} This group of cases was no exception to that statement. Table 2 illustrates this very well. There were 17 men and three women.

Duration of Disease Of this group, 18 died and two survived. There were 17 necropsies in the fatal cases. Of those who died, it was sometimes difficult to determine the exact duration of the disease, but it was commonly found to be one month to one year after the onset of symptoms, the average duration being from two to four months.

Pathology In seven of the 20 cases there were signs of a large collection of fluid in the pericardium. In the others, the exudate was fibrinous and frequently measured 1 to 3.5 centimeters in thickness. In one there was calcification. Eleven of the cases showed enlargement and tuberculosis of the mediastinal lymph nodes. There was an associated tuberculosis of the lungs in three cases, of the pleura in seven cases, and of the peritoneum and epididymis, each in one. Four of the patients finally died of miliary

* Read before the Annual Meeting of the American Climatological and Clinical Association, Richmond, Virginia, October 27, 1936.

It would appear that tuberculosis of the pericardium may produce a massive effusion or a thick productive exudate. When death occurs at this stage, tuberculous tissue is abundant and easily recognized. When the lesion heals, there is organization of the granulation tissue with or without calcification.

Under the term primary tuberculosis of the pericardium, there are described cases¹ in which the pericarditis seems to be the oldest and, in some, the only tuberculous lesion found at necropsy. In the present series of cases, the lesion in the pericardium appeared to be the oldest in twelve. In several the pericardium had become involved as a result of a rupture of a caseous lymph node directly into the pericardial sac. In others, there was evidence that the process had extended to the pericardium from the pleura, the lung, or even the peritoneum. Since practically all infections of the serous membranes result from an extension of an infection directly to them, it is not surprising to find that pericardial tuberculosis arises in this way. When the lesion of the pericardium is the oldest one and the disease is confined to the pericardium, death results from the signs of a wasting disease or cardiac insufficiency, or it may be found accidentally during the course of another disease. Very often, however, the process spreads beyond the pericardium so that there is multiple serous membrane involvement or miliary tuberculosis. In these, the clinical picture is that of multiple serous membrane tuberculosis, cardiac insufficiency, or miliary tuberculosis, or all three. These various aspects of infection will be taken up separately.

GENERAL FEATURES

Fever The febrile reaction was a conspicuous feature in 13 of the 20 cases. It was the outstanding characteristic of the patients with only the signs of a wasting disease and equivocal pericardial signs. In the patients with circulatory failure with congestion, fever was absent in four of the

eight cases. In those with a pericardial effusion, only one remained fever-free during the period of observation. In two of the cases in which the condition was latent and therefore probably terminal, there was no fever. In the febrile cases the daily fluctuation ranged between 99° and 101° , 102° , or even 103° . In essence, then, the presence of irregular fever in patients with heart failure, especially elderly individuals with signs suggesting pericardial disease, should point toward the possibility of tuberculosis of the pericardium.

White Blood Cell Count Anemia was not a feature in these cases. The red blood count and hemoglobin content were reduced in four. In the others they were normal. One patient had chronic nephritis. As is the case in other types of tuberculosis, there was nothing absolutely characteristic about the total white blood cell count. There were wide variations. It was below 5,000 in five, between 5,000 and 10,000 in seven, 11,000 and 15,000 in five, and above 15,000 per cubic millimeter in three. There was nothing distinctive about the differential count although the lymphocyte-monocyte ratios were not studied in detail.

Cardiac Arrhythmias Auricular fibrillation was present in three cases, partial heart block in one. In the others, there were no detectable abnormalities by physical examination. It was not uncommon to observe a low voltage with inversion of the T-waves. Paroxysmal auricular fibrillation has been observed by Dillon,³ and others.⁴

Signs of Congestive Heart Failure There was peripheral edema in 10 cases, ascites in eight, and pleural effusion in nine. In seven of the nine cases of pleural effusion, it was finally demonstrated that tuberculous pleurisy was present, so that one was in fact dealing with multiple serous membrane infection. The pleural effusion was unilateral in five, bilateral in three, and interlobar in one. In two cases such effusions were present without peripheral edema or ascites. In both of these cases the pericardial involvement was indicated by a well marked friction rub, and in one the interlobar pleurisy with effusion was discovered only by roentgen-ray examination. In three cases the pleural effusion was due to venous stasis, as attested by the character of the fluid, and by the absence of tubercles in the pleura at necropsy. In one of these cases there was an effusion on one side due to venous stasis and a productive tuberculosis on the other side. In the remaining five cases, which include one of the previous group where both stasis and tuberculosis were present, there was tuberculosis of the pleura to account for the effusion.

Of the eight cases showing ascites, two showed no peripheral edema, in one the ascites was due to tuberculosis of the peritoneum. In six, the ascites was a part of the general edema.

Summing up, then, it can be asserted that the edema may be general. When there is an associated pleural effusion with or without peripheral edema, it is highly probable that there is an associated tuberculosis of the

pleura. This can usually be determined with precision by studying the aspirated pleural fluid.

When ascites exists it is seen most often in association with peripheral edema, and the fluid has the characteristics of a transudate. Much more rarely, the effusion is due to tuberculosis of the peritoneum, but one may see cases with evidence of heart failure, with tuberculosis of the pericardium and of the pleura, and with a transudate in the peritoneal cavity. Only after a careful study of the fluid can the final decision be reached. Predominant ascites as a manifestation of heart failure was present in only one case in this group.

Blood Pressure. In pericardial disease, especially when there is cardiac compression, it is not infrequent to find a low systolic blood pressure and a low pulse pressure, particularly when the signs are acute. If one excludes two cases in which there was an associated hypertension, the blood pressure in this group was normal or below the average accepted normal for the age group. The systolic pressures varied from 90 to 135 mm. of mercury, and the diastolic pressures from 50 to 88 mm. of mercury. It is obvious that there is nothing absolutely characteristic about the average blood pressure findings. More important in diagnosis is a gradually declining blood pressure with a small pulse pressure, in the face of a rising venous pressure. These are indications of cardiac compression and should direct one's attention to the pericardium.

Pulse Rate. Increase in the pulse rate was the rule, 100 to 120 per minute being common. This is understandable on two grounds: first, because the metabolic requirements are increased due to the infection and, second, because it is only by means of an increased rate that the heart can maintain the output per minute when there is a decrease in diastolic filling. Pulsus paradoxicus was noted on several occasions.

Local Signs Over the Pericardium. The points of diagnostic importance in the physical examination are the determination of the size and configuration of the heart, the presence or absence of a friction rub, the presence of arrhythmias or murmurs, and the quality of the breath sounds. In this group of 20 cases, the transverse diameter of the heart, as determined by roentgen-ray examination, varied from 14 to 22 centimeters. The most conspicuous widening was present in those individuals showing effusions, of which there were seven. True dextrocardia was existent in one. The amount of fluid varied from 700 to 3,500 cubic centimeters. A friction rub was heard in only five cases, and it persisted anywhere from two days to three weeks. The apex beat was either feeble or not obtainable, and the sounds distant and faint. Murmurs were absent, and arrhythmias were present in three cases. These signs then may be summed up by saying that the important ones are an increase in the transverse diameter of the heart, the signs of an effusion, a pericardial friction rub, and a feeble apex beat with distant heart sounds without murmurs.

Roentgen-Ray Examination There is nothing characteristic in the roentgen-ray findings. There may be the classical signs of a pericardial effusion or merely a widening of the cardiac shadow. The fluoroscopic examination may reveal a diminished pulsation of the ventricles. This is more significant when the size of the heart is small, since it indicates an interference with diastolic filling.

The Character of the Pericardial, Pleural, and Ascitic Fluid The fluid may be straw-colored or hemorrhagic. When there is a simple transudation of fluid due to venous stasis, the fluid has the characteristics of a transudate. There is one condition, however, in which a transudate assumes the characteristics of an exudate, insofar as the protein content is concerned, and that is following a copious diuresis that has been induced by drugs. I have seen the protein content of a pleural fluid increase from 1 to 4.5 per cent following diuresis. The circumstances under which the fluid is examined must therefore be taken into account.

The fluid may be hemorrhagic and, in this respect at least, resemble the fluid from rheumatic fever exudates, or from those resulting from metastatic tumors in the serous membranes. From experimental studies⁵ we know that hemorrhagic fluids in tuberculosis are more likely to contain tubercle bacilli, since large numbers of tubercle bacilli injected into the serous membranes of a sensitized animal frequently result in a hemorrhagic exudate.

The presence of tubercle bacilli as determined by guinea pig inoculation or by direct examination makes the diagnosis positive. Without this, the fluid findings are not absolutely decisive. The important point to determine is whether the fluid is an exudate or a transudate, since in tuberculosis of the pericardium there may be a transudate or an exudate in the other cavities depending upon the presence of infection, or stasis, or both.

The cell count is increased and the cells are usually of the mononuclear or lymphocytic variety.

Symptoms It is convenient for purposes of discussion to divide the cases into several groups, depending upon the symptomatology and the clinical course of the disease. This division is more or less arbitrary since one group may gradually begin to show the signs which are considered characteristic of another. This is not surprising since such merely indicate various phases of the same disease process. The outstanding clinical features depend upon the pathogenesis, mode of spread, the type of pathological process causing the functional disturbance, and the duration and stage of the disease. The following subdivision of cases has been adopted:

- 1 Patients with symptoms and signs of a wasting disease and obscure fever
- 2 Patients with symptoms and signs suggesting heart failure with congestion
- 3 Patients with symptoms and signs of multiple serous membrane tuberculosis

- 4 Patients with symptoms and signs of a massive pericardial effusion
- 5 Patients with symptoms and signs of miliary tuberculosis

PATIENTS WITH SYMPTOMS AND SIGNS OF A WASTING DISEASE AND OBSCURE FEVER

There were five patients in which these signs were the outstanding features of the illness. The following case report is an example.

Case 12 A man, aged 70 years, complained of shortness of breath and weakness. His past and family histories were inconsequential and he had always enjoyed relatively good health. For a period of two years he had felt some constriction across his chest after exertion which was relieved by rest. Aside from this, he had no discomfort until two months before he was seen. At that time he began to notice progressive weakness, loss of weight, insomnia, and some shortness of breath on exertion. Several days before admission to the hospital he had some pain over the lower part of the chest which was not severe and did not radiate. The examination showed an elderly man, with moderate dyspnea, resting quietly. There was no orthopnea. He obviously had lost weight but his skin and mucous membranes were of normal color. The positive findings were confined to the examination of the heart. There was some tenderness of the skin over the precordium, the heart measured 10 centimeters to the left and 7 centimeters to the right of the mid-sternal line by teleroentgenogram. The sounds were distant but without murmurs, and the apical impulse was feeble. A short superficial friction rub was heard over the precordium. The blood pressure was 145 mm. of mercury systolic, and 65 mm. of mercury diastolic. The lungs were clear, the abdomen and extremities negative.

Laboratory Examinations The electrocardiographic examination showed a normal mechanism with no abnormalities in conduction. There was no anemia, and the leukocyte count was 5,900 per cubic millimeter. The differential was normal.

Course of the Disease After two days, the pericardial friction rub disappeared and never returned. The temperature was elevated, and varied from 100° F. to 103° every day. The patient showed signs of progressive weakness and loss of weight. The blood pressure did not change, there were no signs of congestive heart failure or increased venous pressure. The area of cardiac dullness remained wide and the heart sounds became more and more distant until they could be heard with difficulty. The apex beat could not be felt. He finally had an attack of rapid heart rate with collapse and died in coma. The total duration of his illness was 12 weeks from the onset of symptoms. The necropsy showed a tuberculosis of the pericardium with thick fibrinous exudate. The heart was of normal size. There were numerous enlarged mediastinal lymph nodes, one had extended directly into the pericardial sac. There were no signs of active tuberculosis elsewhere.

In brief, then, the salient features were those of a febrile illness in an elderly man, with a transitory pericardial friction rub and an increase in the area of cardiac dullness, a feeble apex impulse and distant heart sounds. His course was one of progressive weakness with the features of a chronic febrile wasting disease. Necropsy demonstrated that the sequence of events had been the rupture of a caseous mediastinal lymph node into the pericardial sac and an extensive tuberculous infection of the pericardium. At no time were there any signs of increased venous pressure.

These patients have the symptoms and signs which are common to any

chronic infection (fever, progressive weakness, loss of weight, anorexia, malaise, etc.) In addition, there may be symptoms referable to the chest, with pain and constriction over the precordium and shortness of breath. The physical examination may reveal a pericardial friction rub, but the chief features may be signs which are compatible with a thickening of the pericardium, i.e., feeble apex beat, distant heart sounds, and an increase in the transverse diameter of the heart. In any event, it should be recalled that obscure fever in the elderly may be due to a tuberculosis of the pericardium.

PATIENTS WITH SYMPTOMS AND SIGNS OF CARDIAC INSUFFICIENCY

When there is a compression of the heart or great vessels resulting from an exudate in the pericardium, there is an obstruction to the inflow of venous blood, and circulatory failure with congestion follows. When pericardial disease appears in the elderly there is often another disease present, namely, coronary arteriosclerosis. The changes in the circulation which follow pericardial disease often increase the difficulty of supplying sufficient blood to the heart. The low mean arterial pressure, the low cardiac output, and low stroke volume will all tend to decrease coronary circulation. In addition, in some cases, as those reported by Bellet, Gouley, and McMillan,²⁰ there exists definite arteritis with occlusion of the coronary vessels which would naturally decrease the coronary circulation further. It is not surprising, then, that once circulatory failure sets in it is progressive and there is rarely any improvement. These patients complain of a sense of constriction in the chest on exertion that is relieved by rest. They exhibit edema, shortness of breath, cough, and progressive weakness. Early in the course of the disease there may be very little pulmonary congestion. The dyspnea in these cases is probably due in part to the increase in the venous pressure in the great veins through a reflex mechanism, as described by Harrison.⁷ Later, there are signs of pulmonary congestion. But, as I have stated, effusions into the pleural cavity in active tuberculosis of the pericardium are likely to be due to an infection of the pleura rather than a transudate. Finally, the disease is not infrequently terminated by a miliary tuberculosis. In this group of eight patients with progressive heart failure, there was fever in four, pleural effusion in seven, tuberculosis of the pleura in five, ascites with edema in six, and ascites without edema in one. Miliary tuberculosis was present in three. The following case illustrates the course of events in a typical case.

Case 9 This white man, 74 years of age, was seen first in December 1934. At that time he complained of failing health for two or three months. This was characterized by weakness, shortness of breath on exertion, orthopnea, and edema of the lower extremities, genitalia, and abdomen. He had always enjoyed good health until the present illness.

The physical examination showed a small man with evidence of loss of weight. The skin was dry and scaly over the upper part of the trunk and arms. The mucous membranes were of normal color. The examination of the head revealed no abnormalities. The neck veins were moderately distended. The chest was small, moved

as a whole, and showed a senile kyphosis. There were moist râles at both lung bases, and the signs of a hydrothorax in the left pleural cavity. The heart borders were difficult to define by percussion. The apex beat was not visible or palpable. The sounds were distant and feeble in quality. There were no murmurs or friction rub. The aortic second sound was louder than the pulmonic second sound. The abdomen was distended with fluid, and there was a distinct fluid wave on percussion. No other abnormalities were found. There was massive pitting edema over the sacrum and back, lower part of the abdominal wall, and genitalia. The temperature was normal, the pulse rate varied from 100 to 110 per minute. The respirations were 32 per minute. The blood pressure was 110 mm of mercury systolic, and 75 mm of mercury diastolic.

Laboratory Examinations The urine showed neither albumin nor sugar. The white blood cell count was 4,250 per cubic millimeter. The total protein of the blood plasma was 5.7 per cent. The ascitic fluid had the characteristics of a transudate. The specific gravity was 1.012. There were 23,000 cells per cubic millimeter, of which 500 were white blood cells and the remainder were erythrocytes. The differential count of the white cells showed 80 per cent lymphocytes and 20 per cent monocytes.

Roentgenogram of the chest showed the heart to be enlarged to the left, and there were signs of fluid at the left base. There was evidence of an old tuberculous process at both apices.

Electrocardiographic examination revealed a left ventricular preponderance with a low amplitude of the QRS complexes.

Course of Illness The patient failed gradually for a period of 11 weeks. The usual treatment for congestive heart failure was unsuccessful in relieving his edema. During the last week of his illness there were fever, cough, and an increase in the râles throughout his lungs. He died five months after the onset of symptoms of heart failure. The anatomical diagnoses were Tuberculosis of the pericardium—containing 300 c.c. of sero-sanguinous fluid, miliary tuberculosis of lungs, liver, spleen, coronary arteriosclerosis, cardiac enlargement.

To sum up, an elderly man developed heart failure with congestion which was progressive without remission over a period of five months. The entire course was afebrile except for the last week of his illness when there was irregular fever and cough. Necropsy demonstrated the cause of his illness to be due to tuberculosis of the pericardium and a terminal miliary tuberculosis.

MECHANISM FOR THE PRODUCTION OF CIRCULATORY FAILURE WITH CONGESTION IN PERICARDIAL DISEASE

From the careful observations of a number of observers, we are now able to understand the mechanism which produces circulatory failure in patients with pericardial disease. Experiments have been done on animals with acute and chronic pericardial disease,^{8, 9, 10} and quantitative studies of the circulatory functions have been carried out in man with the same disorder. The type of circulatory failure which is seen in pericardial disease has been called "inflow stasis" by Volhard.

In the case of an acute distention of the pericardium with an inflammatory exudate or with blood, the pericardium stretches very slowly so that

the increasing pressure within the pericardial sac causes cardiac compression, with a falling systolic blood pressure, a rising venous pressure, enlargement and depression of the liver Beck¹¹ has stated that a pressure equal to 16 centimeters of water, acutely applied to the heart, may be fatal This external pressure on the auricles interferes with the inflow of blood from the periphery and an inadequate filling of the heart results in insufficient output to maintain life When the process in the pericardium is more chronic and produces compression of the heart by fibrous tissue, the pressure within the great veins may attain very high levels Such individuals, in addition to the increased venous pressure, show enlargement of the liver with ascites No cardiac enlargement is present, although it may be suggested by an increase in the transverse diameter of the heart

From a quantitative study of the dynamics of the circulation in *constrictio cordis*, Burwell, Strayhorn and Flickinger^{12,13} have stressed the following points At rest, these individuals show a low pulse pressure, a rapid pulse rate, an elevation of the general venous pressure, a low circulatory minute volume, and a reduced stroke volume The oxygen utilization is high but the oxygen saturation of the arterial blood is normal, and there may be a normal or only slightly reduced vital capacity

Following exercise, the oxygen consumption increases but the pulse pressure and stroke volume remain unchanged The pulse rate accelerates and the circulatory minute volume increases in proportion to the rate Venous pressure increases and cyanosis is clearly visible

The exhibition of digitalis causes a slowing of the rate and a decrease in the cardiac output In brief, it appears that the only method of increasing the blood supply to the tissues is through increasing the heart rate It is not possible to increase the stroke volume, since the heart is prevented from receiving more blood during diastole

PATIENTS WITH SYMPTOMS AND SIGNS OF MULTIPLE SEROUS MEMBRANE TUBERCULOSIS

It is common knowledge that tuberculous infections of the serous membranes are very often multiple The results of the present study were confirmatory of this rule As has been related already, seven of the patients had a tuberculous pleurisy, and one had an associated tuberculosis of the peritoneum The finding of tuberculosis of the pleura or peritoneum may aid in the etiologic diagnosis of the pericardial lesion, particularly if the signs are equivocal and circulatory failure is present The case report which follows indicates the course of events in one of the cases

Case 7 An 81 year old man complained of pain in the back of three weeks' duration His family and past histories were non-contributory He regarded himself as well until a year before he was seen, when he had an infection which was called the gripe It was characterized by malaise and weakness but there was no dyspnea Since then he had had several small hemoptyses at varying intervals A

few months before he was admitted to the hospital he began to notice dyspnea and tightness across the chest on exertion, which were relieved by rest. These symptoms progressed for three weeks, then he developed an acute respiratory infection with generalized aches, pains, and prostration. For a week he had experienced attacks of paroxysmal nocturnal dyspnea accompanied by cough. There were also weakness and anorexia.

The examination revealed a temperature of 101° F, pulse rate 98 per minute, respirations 24 per minute. The blood pressure was 105 mm of mercury systolic and 75 mm of mercury diastolic. He was a pale, elderly man with some increase in the respiratory rate without distress. The examination of the head revealed nothing abnormal. The lungs showed impaired resonance and râles at the base of the left lung. The right side of the chest revealed evidence of a pleural effusion. The heart was enlarged to both the right and left, the transverse diameter being 15 centimeters. The rate was rapid and totally irregular, the sounds were very faint, and all over the lower part of the sternum there was a to-and-fro friction rub. The liver was slightly enlarged below the costal margin, otherwise the abdomen was negative. There was no edema of the legs.

Laboratory Examinations The urine was negative. The red blood cell count was 3,900,000 per cubic millimeter, hemoglobin 78 per cent (Sahli), and the white blood count was 7,400 per cubic millimeter. The Kahn reaction was negative. The non-protein nitrogen was 30 milligrams per cent, and the total protein of the blood plasma 5.2 per cent. The sputum was negative for tubercle bacilli. The pleural fluid had a specific gravity of 1.017. The cell count per cubic millimeter was as follows: red blood cells 3,810, lymphocytes 110, mononuclears 580. There was a great increase in the fibrin.

Course of Illness After three days the temperature fell to normal and finally to subnormal after several weeks. With rest and digitalis the ventricular rate was reduced. The electrocardiogram showed auricular fibrillation and low voltage. The tuberculin test in a dilution of 1:1,000 was positive. The pericardial friction rub disappeared after two weeks. The heart sounds remained distant and weak. There were rapidly recurring effusions into the right chest. He failed gradually and died after a period of nine weeks' observation.

The necropsy revealed tuberculosis of the pericardium, bilateral tuberculosis of the pleura, and pulmonary tuberculosis with a small cavity in the right lung.

There was no doubt, in this case, that the process began in the lung and then extended to the pleura and pericardium. At no time were there signs of heart or circulatory failure. It was a clear example of serous membrane tuberculosis in an elderly man.

PATIENTS WITH SYMPTOMS AND SIGNS OF A MASSIVE PERICARDIAL EFFUSION

It is universally recognized that one way in which the pericardium responds to a tuberculous infection is by the exudation of copious amounts of fluid which is frequently hemorrhagic. A pericardial effusion was found in seven of the 20 cases and varied from 700 to 3,500 cubic centimeters. All but one had fever. Three of these patients showed circulatory failure, the other four did not. It is perhaps worthy of comment that the two patients in the entire group who survived were young, with a moderate collection of pericardial fluid and no signs of cardiac compression. In one the effusion was accompanied by tuberculosis of the peritoneum, in three there was an associated tuberculosis of the pleura, and in one the disease terminated with

a miliary tuberculosis. There was nothing peculiar about the physical signs of the pericardial effusion and they were all characteristic. It does not seem unreasonable to suppose that the patients who have a poor outlook in this group are those who develop cardiac compression or an associated tuberculosis of the pleura or peritoneum. Conversely, the ones who are likely to improve are young individuals with a small effusion, without cardiac compression or signs of tuberculosis elsewhere. The following case illustrates the course of events in these cases.

A man, 70 years of age, was apparently healthy until two weeks before entry to the hospital, when he had a sudden acute pain in the left side which was severe and exaggerated by respiratory effort. Soon thereafter, shortness of breath on exertion and edema of the legs and abdomen appeared.

Examination showed a man with moderate cyanosis but without respiratory distress. The head, nose, and throat revealed nothing abnormal. The veins of the neck were greatly distended. The lungs were everywhere clear except for a number of moist rales at both bases. The heart measured 17 centimeters in its transverse diameter. The apex beat was not palpable, the sounds were feeble and distant, and there was a loud friction rub over the precordium. The liver was enlarged 6 centimeters below the costal margin, the abdomen was distended with fluid. There was massive edema of the genitalia, legs, and feet. The temperature varied from 101 to 102° F. The pulse rate varied from 90 to 100, the respiratory rate from 25 to 40 per minute.

Laboratory Examinations. The urine showed a trace of albumin and a rare hyaline cast. The pericardial fluid was serosanguinous with 6,000 red blood cells per cubic millimeter and 400 white blood cells, of which 80 per cent were lymphocytes and 20 per cent were monocytes.

Course of the Disease. During the first seven weeks of observation the temperature was elevated for five weeks, and then remained normal for two weeks. The pericardium was tapped on three occasions, and 650, 1,000 and 400 cubic centimeters withdrawn. There was temporary improvement but by the ninth week his dyspnea and edema were increasing. The veins of the neck became greatly distended. The signs over the heart remained the same but there appeared definite evidences of an effusion of fluid into the left pleural cavity. The abdomen was distended, the liver enlarged, and the edema and cyanosis were generalized. There was a pleuro-pericardial friction rub. The fluid from the left side of the chest had the same characteristics as that from the pericardium. The temperature remained normal, the pulse and respiratory rate were elevated. He failed rapidly and died three and one-half months after the onset of symptoms.

The anatomical findings were tuberculosis of the pericardium with an effusion of 550 cubic centimeters of serosanguinous fluid, tuberculous pleurisy with effusion of 900 cubic centimeters of fluid, generalized miliary tuberculosis of the lungs.

In a word, an elderly man with tuberculosis of the pericardium and a large effusion developed circulatory failure due to an increase in the general venous pressure. As the disease progressed, the left pleural cavity became involved and disseminated tuberculosis of the lung appeared as the final event. This case illustrates how a pericardial effusion may cause circulatory failure, and demonstrates the dangers of a spread to the pleura and of disseminated tuberculosis.

PATIENTS IN WHOM TUBERCULOSIS OF THE PERICARDIUM IS A TERMINAL EVENT IN THE COURSE OF ANOTHER DISEASE

There were three patients in whom tuberculosis of the pericardium was a terminal event, two had cirrhosis of the liver and one had chronic nephritis. Cardiac insufficiency was present in two, but there was no evidence that the pericardial lesion was responsible for the heart failure except in the one patient with cirrhosis of the liver. The latter case follows.

Case 14 This 55 year old man was first seen in October 1934 when he complained of anorexia, nausea, and vomiting of three weeks' duration. There had been frequent bowel movements for one week. The point of significance in his past history was the fact that he had used large amounts of alcohol for about 32 years.

The physical examination showed a man with fever which fluctuated between 99 and 101° F every day. He had lost weight but did not appear pale. The lungs were clear and the heart was not enlarged. The sounds were clear and no friction rub was heard. The peritoneal cavity was filled with fluid. There was no edema of the legs.

Laboratory Examinations The white blood count varied from 4,200 to 15,000 per cubic millimeter. The ascitic fluid on two occasions had the characteristics of a transudate, a specific gravity of 1.003, white blood count of 108 per cubic millimeter and red blood count of 372 per cubic millimeter. Roentgen-ray of the chest showed that the lungs were clear and the heart not enlarged. An electrocardiogram revealed left ventricular preponderance and auricular fibrillation.

Course of the Disease Four weeks after he was first seen, he commenced to have shortness of breath, increasing anorexia, and edema of the legs and abdomen. He was slightly jaundiced and râles appeared at the lung bases. The heart reverted to a normal sinus rhythm with a partial heart block. The edema progressed and he died two weeks later.

The necropsy findings were tuberculosis of pericardium, alcoholic cirrhosis of the liver, chronic duodenal ulcer, ascites.

In this case, the tuberculosis of the pericardium was a terminal event in a patient with cirrhosis of the liver. The cirrhosis was outstanding.

PATIENTS IN WHOM TUBERCULOSIS OF THE PERICARDIUM IS FOLLOWED BY MILIARY TUBERCULOSIS

Disseminated tuberculosis following tuberculous infection of the pericardium is not infrequent. It was present in five of our cases. The cases in which the pericardium was involved as a part of a disseminated infection were, of course, not included in this study since they gave no evidence of pericardial disease during life. Others have commented on the frequency with which tuberculosis of the pericardium is followed by dissemination of the disease and this sequence undoubtedly is responsible in part for the high mortality. In some cases the whole course of the disease is afebrile and the finding of miliary tubercles everywhere comes as a complete surprise.

COMMENT

Taking the evidence as a whole, the clinical features of tuberculosis of the pericardium may be reviewed as follows. The diagnosis should be entertained, especially in elderly individuals, when there are symptoms and signs of an infection with localizing signs indicating a lesion of the pericardium. There may be only a pericardial friction rub of short duration, or unmistakable evidence of a pericardial effusion, and of cardiac compression with peripheral venous stasis and edema. It perhaps should be emphasized that in some patients the signs of infection predominate and the evidence for a lesion of the pericardium is very meager. It may consist only of a feeble apex impulse and distant heart sounds, signs which, in themselves, are certainly not always compatible with disease of the pericardium. It is also worthy of comment to say that there may be the signs of "inflow stasis" or peripheral edema indicating pericardial disease without signs of an acute infection.

If the process spreads from the pericardium to the pleura or if there are signs of tuberculosis of the peritoneum or the lungs at the same time, then the diagnosis is much simpler. Finally, one should remember that miliary tuberculosis in the elderly may begin as tuberculosis of the pericardium.

Differential Diagnosis In my experience, the diseases with which tuberculosis of the pericardium have been confused most often are (1) coronary artery disease with consequent heart failure, (2) cirrhosis of the liver, (3) rheumatic pericarditis.

Coronary Artery Disease In elderly individuals who complain of constriction in the chest and symptoms suggesting cardiac insufficiency without evidence of valvular disease or hypertension, the diagnosis of coronary artery disease is most often entertained. If this is accompanied by precordial pain that is followed by fever and a pericardial friction rub, the temptation to make the diagnosis of a coronary occlusion with myocardial infarction is great. Even in the absence of a friction rub, the signs over the heart may be similar in the two conditions under discussion, that is, the heart sounds are distant and the apex impulse feeble. This is particularly true of patients with coronary occlusion who have developed an aneurysm of the left ventricle following infarction. One point of difference may be helpful in these cases. The impulse after coronary occlusion is more likely to be well felt but the heart sounds are feeble and there is often a gallop rhythm present, whereas in pericardial disease, the apex impulse and the sounds are both distant. In addition, the roentgen-ray diagnosis of an aneurysm of the left ventricle may aid in the differentiation.¹⁴ The electrocardiogram may be helpful but it is not always decisive since changes in the T-waves similar to those occurring in coronary occlusion are reported in cases of pericardial disease. The differentiation must be made largely on the basis of the clinical course of the disease, a careful analysis of the history, and the various physical and other findings.

Cirrhosis of the Liver Inasmuch as two of the cases described had an

alcoholic cirrhosis of the liver and a terminal tuberculosis of the pericardium, both conditions may coexist in the same individual. In the one case, the cirrhosis was limited in extent and therefore latent. In the other, the symptoms and signs were predominantly those of cirrhosis, and the diagnosis of tuberculosis of the pericardium was latent and disclosed by the pathologist.

The instances in which tuberculosis of the pericardium is likely to be confused with cirrhosis of the liver are those in which there is an insidious onset with progressive signs of stasis, and ascites which is disproportionate to the other evidences of increased venous pressure. This is the picture that is seen most often in *concretio cordis* with or without calcification of the pericardium, and it is not seen so often in the more acute type which has been described in this paper.

It is convenient at this point to say something about so-called "cardiac cirrhosis," since this is the condition seen as a result of repeated attacks of heart failure and chronic venous stasis. It should be clearly distinguished from other types of hepatic cirrhosis, since it is highly doubtful whether the alterations in the structure of the liver in chronic stasis are of sufficient degree to cause portal obstruction. It consists of a central necrosis, usually of the hemorrhagic type. The necrotic cells are removed by macrophages and, if no regeneration takes place, the stroma of the liver gradually contracts, resulting in areas of sclerosis around the central veins. As a result of this process the liver is diminished in size and its surface finely and evenly granular. It is to a liver at this stage that the name "cardiac cirrhosis" has been given.

In a certain number of cases, perhaps due to a stimulus of an unusually extensive central necrosis or repeated attacks of congestion, very active regeneration of liver cells takes place. If these areas of regeneration surround the sublobular veins, they tend to be roughly circular in outline. If they follow the radicles of the portal vein, they have a curious branching arrangement which has been likened to a fern leaf. When Youmans and Merrill¹⁵ collected and reported the cases of pericarditis calculosa several years ago, they called attention to the fact that at least one-third of the reported cases were associated with an "atrophic" cirrhosis of the liver. They were not of the opinion that the cirrhosis of the liver in these cases resulted from chronic venous stasis, but that it was a further expression of the fundamental disease process which, in most cases, was tuberculosis. Without more details of the histologic changes in the liver being available, it is impossible to say whether the changes observed in the liver in cases of pericarditis calculosa are the result of chronic stasis or not.

One of the most reliable tests for discriminating between cirrhosis of the liver and "inflow stasis" is the general elevation of venous pressure. That is to say, the venous pressure is increased in both the veins of the upper and lower extremities in pericardial disease, whereas in cirrhosis of the liver the venous pressure of the legs may be increased in the presence of ascites but

the pressure in the veins of the arms is normal or only slightly elevated. The presence of other signs of portal obstruction is often more conspicuous in cirrhosis of the liver. It is perhaps worthy of comment that patients with limited cirrhosis of the liver may die of heart failure, as in the cases reported by McCartney.²¹ This was true in 25 per cent of the cases. In most of the cases the cirrhosis of the liver played no part in the clinical picture.

One may sum up the discussion by saying that patients with latent or advanced cirrhosis of the liver may develop tuberculosis of the pericardium as a terminal event. It is also recognized that venous stasis resulting from pericardial disease may produce secondary anatomical changes in the liver. The relative importance of these changes in the production of ascites cannot be assessed at present. Certainly, recurrent ascites is observed without any change in the liver other than chronic passive congestion. Finally, it is not uncommon for patients with latent cirrhosis of the liver to die as a result of independent heart disease. The cases in which confusion most often arises are those with recurrent ascites and an increase in general venous pressure. The last feature is of the highest importance in differential diagnosis.

Rheumatic Heart Disease The appearance of tuberculosis of the pericardium in the younger age groups requires differentiation from rheumatic heart disease. In some this is not difficult, especially if there is an associated arthritis or if there are signs of valvular disease, or changes in conduction by electrocardiographic examination. When tubercle bacilli can be obtained from the pericardial fluid or when tuberculosis exists elsewhere then the diagnosis is less difficult. However, when the fluid fails to contain demonstrable tubercle bacilli it is not possible to make the discrimination on the basis of the characteristics of the fluid alone. They both have the characteristics of an exudate, contain large amounts of fibrin and an increase in cells, and both of them may be hemorrhagic. In a few, the diagnosis can be made only from a study of the course of the disease. I have seen several patients who had been sent to tuberculosis sanatoria on account of pleurisy and pericarditis with a hemorrhagic fluid who returned after two years with unequivocal signs of mitral stenosis. This was excellent testimony that the original disease was rheumatic fever.

It is perhaps well to recall that while disturbances in rhythm or conduction are not common in tuberculosis of the pericardium, they have been observed, so that this sign alone does not favor the diagnosis of rheumatic heart disease. It has been suggested by Bellet, Gouley, and McMillan that the presence of arrhythmias may suggest tuberculous disease of the heart muscle, especially of the right auricle.

Speaking broadly, the diagnosis of rheumatic pericarditis may not be difficult in most cases, in the few in which tuberculosis is suspected, the various points mentioned above should prove helpful.

PROGNOSIS AND TREATMENT

From the study of these cases and others reported, it is difficult to escape the conclusion that tuberculosis of the pericardium is a most serious disease. The reasons would appear to be the age at which it is common, the tendency to multiple serous sac infection or disseminated tuberculosis, and the fact that the location of the lesion interferes with the functions of the circulation. That some patients recover and survive a number of years without difficulty, there seems to be little question. But even when there is healing of the pericardial lesion the end result may be cardiac compression resulting from the constriction of the heart by fibrous tissue with or without calcification.

Within recent years, striking advances have been made in the surgical treatment of *concretio cordis*^{10, 11, 13, 16, 17}. The best results have been obtained in relatively young individuals who have a fibrous pericardium without signs of an active infection. In the cases of *concretio cordis* in which active tuberculosis has been found at the time of operation, the results have been unsatisfactory. Although the reported experience with surgical treatment is limited, it would seem justified to say that operation in the face of an active infection has little to offer.

Another method that has been used is the injection of air or oxygen into the pericardial cavity following the aspiration of fluid^{18, 19}. The purpose of this is to prevent the development of adhesions. The only case in which I have seen this method used resulted in failure and the patient died.

There is no doubt that the pericardium should be tapped in the patients who show signs of cardiac compression, provided the compression is due to a pericardial effusion and not a fibrous exudate. A falling systolic pressure, a rising venous pressure, and clinical signs of venous stasis are indications for pericardial tapping.

SUMMARY AND CONCLUSIONS

From a study of 20 cases of tuberculosis of the pericardium, the following conclusions are justified:

1. Tuberculosis of the pericardium is seen most often in patients over 40 years of age, and it is essentially a disease of the elderly.
2. Patients frequently present themselves with
 - a. Symptoms and signs of a wasting disease and obscure fever
 - b. Edema and congestion simulating cardiac insufficiency
 - c. Multiple serous membrane infections
 - d. Miliary tuberculosis
3. It may occur as a terminal event during the course of another disease.
4. The diagnosis may be entertained when there are
 - a. Symptoms and signs of an infection
 - b. Localizing signs over the pericardium, such as—

- (1) Pericardial friction rub
- (2) Pericardial effusion
- (3) Signs of thickening of the pericardium
- c Signs of circulatory failure which is predominantly of the "inflow stasis" type
- d Signs of extension of the process to the other serous sacs, or a disseminated tuberculosis
- 5 It may be confused with
 - a Coronary artery disease
 - b Cirrhosis of the liver
 - c Rheumatic pancarditis
- 6 Tuberculosis of the pericardium arises from an invasion of tubercle bacilli from the mediastinal lymph nodes, the lungs, the pleura, or peritoneum
- 7 The prognosis is always serious, and present methods of treatment are unsatisfactory

FULMINATING SEPTICEMIA ASSOCIATED WITH PURPURA AND BILATERAL ADRENAL HEM- ORRHAGE (WATERHOUSE-FRIDERICHSEN SYNDROME); REPORT OF TWO CASES WITH REVIEW OF THE LITERATURE

By MILTON S SACKS, B S , M D , *Baltimore, Maryland*

THE occurrence of adrenal hemorrhages of varying degree is a matter of common clinical and pathological knowledge in such conditions as diphtheria, scarlet fever, measles, and pneumonia. In new-born and still-born infants, adrenal hemorrhage, likewise, is known to occur and is chiefly of mechanical or traumatic origin. Snelling and Erb¹ found 43 cases of adrenal hemorrhage in 3,637 consecutive autopsies, an incidence of 1.19 per cent. Of these, 15 occurred in the new-born. In older children, adrenal hemorrhage is usually of toxic or infectious etiology.

The association of fulminating purpura with bilateral adrenal hemorrhage has long been recognized. The earliest case reports of this condition are to be found in the English literature. Garrod and Driysdale,² Voelcker,³ Still,⁴ Batten,⁵ Talbot,⁶ Blaher and Bailey,⁶ were among the first to note this association, but it remained for Graham Little,⁹ writing in 1901, to recognize and classify such cases as a distinct clinical entity. Waterhouse,¹⁰ in 1911, reported one case and collected 15 from the literature. He attempted to portray a definitive disease picture, but added no knowledge as to the etiology beyond observations concerning a possible bacterial cause, which even earlier observers had suggested. Friderichsen,¹¹ in 1918, in an inclusive review, brought the literature up to date. His clinicopathological picture was quite complete, but he, likewise, added no new information concerning etiology. McLagan and Cooke,¹² in 1916, were perhaps the first to incriminate the meningococcus in two case reports, which fit definitely into the so-called Waterhouse-Friderichsen picture. Since that time there have been several other reports, chiefly in the German literature, notably those by Baumann, 1931,¹³ Glanzmann, 1933,¹⁴ and Bamatter, 1934.¹⁵ The literature is brought up to date by Aegerter¹⁶ in a recent excellent review. He has collected 55 case reports which fit into the clinical picture of this syndrome and in addition presents two of his own. To these may be added three cases presented in a study of meningococcemias by McLean and Caffey¹⁷, another reported by Glanzmann¹⁴ and two cases in a series of suprarenal hemorrhages studied by Snelling and Erb.¹ Foucar²⁶ in a recent report adds still another case which presents a typical Waterhouse-Friderichsen picture.

The sequence of events occurs with sufficient regularity to enable one to

* Received for publication October 20, 1936.

From the Department of Pathology, School of Medicine, University of Maryland.

paint a picture which stamps this syndrome as a clinical entity. The majority of cases occur in young children. In the reported cases the ages varied from two months to nine years with only seven, or approximately 10 per cent, occurring in adults. Forty-five, or 70 per cent, occurred in infants two years or younger. Sex apparently plays no part since the cases occurred with equal regularity in males and females.

The case history, characteristically, tells of a previously healthy child who quite suddenly becomes ill. The early symptoms are non-specific and are such as may occur in any acute infection. Many of the histories state that the child, having gone to sleep, apparently quite well, awakens suddenly during the night with a cry. Vomiting occurs early and frequently but is moderate, and the character of the vomitus is not notable. Hyperpyrexia is present and most cases report a septic type of fever with the upper levels as high as 108° F. Chills occur, but are present infrequently. Diarrhea and abdominal pain, never localized, are, likewise, present occasionally. Central nervous system symptoms appear early and vary from severe headache, in adults, to delirium, restlessness and generalized convulsions in children. The patients soon lapse into a lethargic, stuporous state and remain so until exitus occurs.

Within a few hours after onset a striking cyanosis is noted. This is mentioned in 29 case reports, or 46 per cent, and in two others a peculiar alternation of pallor and cyanosis is reported. The cyanosis is quite out of proportion to the degree of pulmonary involvement, but together with the tachypnea and dilatation of the alae nasae, it has often led to an erroneous diagnosis of pneumonia.

Soon after the appearance of cyanosis a petechial eruption is noted, involving the face, neck, trunk and extremities. The petechiae are bluish-red in color, irregularly shaped, and do not fade on pressure. The conjunctivae often present similar petechiae. They appear quite suddenly and soon become associated with a diffuse, macular, purpuric rash. This latter frequently tends to become confluent and form areas often as large as the palm of one's hand. The skin, thus, has a mottled, livid appearance, not at all unlike postmortem lividity. This rash persists until death occurs.

Examination of the patient reveals an extremely toxic, often comatose child, breathing rapidly and shallowly. The respirations occasionally change in character and become stertorous and of a Cheyne-Stokes variety terminally. At the onset of the illness, the pulse is proportionate to the hyperpyrexia, but later it becomes running, feeble and thready. Physical examination of the chest may reveal moist râles, posteriorly, at the bases. There is no change in cardiac contour, nor does auscultation reveal any changes beyond a sinus tachycardia and enfeeblement of the heart sounds. The abdomen is negative to examination. The extremities reveal only the characteristic rash described above. There are no characteristic neurological findings. Headache may be present and is often quite severe in

adults Cervical rigidity is usually absent, or there may be the faintest suggestion of meningismus present The reflexes are unaltered as a rule

These dramatic events run their course in from 24 to 48 hours The majority of cases terminate in 24 hours or less Other less frequent findings are mentioned in occasional reports, such as a disparity between the high oral and rectal temperatures and a low surface temperature, tremors of the extremities and muscle flaccidity, all as variants from the usual picture

The laboratory offers little help in diagnosis aside from the possibility of finding meningococci in blood smears from purpuric areas as suggested by McLean and Caffey,¹⁷ Netter, Salanier and Wolfrom¹⁸ The former workers were able to demonstrate intracellular gram-negative organisms in smears from the skin lesions in 83 per cent of a series of cases of meningococcus meningitis

Because of the fulminating character of the disease there are few detailed reports of the blood picture There is usually a leukocytosis Varying figures are given from 7,000 to 88,500, the average being about 12,000 There is a definite increase in granulocytes with a shift to the left Three reports mention platelet counts Battley¹⁹ 216,000, Glanzmann mentions a thrombopenia but gives no figure, Bamatter, 172,000 Generalizations cannot be made from these three figures, but in view of the subcutaneous vascular lesions it appears that an adequate explanation of the purpura is at hand without calling upon a thrombocytopenia

Spinal fluid examination usually reveals a clear, colorless fluid with perhaps a slight increase in cells, usually polymorphonuclears Various other constituents of the fluid, such as globulin and sugar, show no change Aegerter notes that of all the patients who were tapped only six showed abnormalities In three there was an increase in cells, in six the meningococcus was isolated, and in four an increase in pressure was present

PATHOLOGY

The outstanding pathological finding is a massive, bilateral adrenal hemorrhage This was present in approximately 95 per cent of the cases Occasionally only one adrenal is involved and when so, it is usually the right The hemorrhage may vary from multiple, pin point areas to a massive type, converting the adrenal into a "blood cyst" Almost always it is confined within the limits of the capsule of the gland In only one of the reported cases was rupture noted to have occurred with a resultant hemorrhagic peritonitis

The histopathology of the adrenals usually merely confirms the gross findings The densest hemorrhage appears to be in the region of the medulla and zona reticularis of the cortex It apparently involves the other layers by diffusion and often leaves a narrow layer of cortical tissue in the zona glomerulosa intact Thrombosis or embolism is rarely seen and an inflammatory reaction is usually absent

The skin lesion is apparently due to direct involvement of capillaries and arterioles by the causative organism. Brown²⁰ found an inflammatory reaction in the capillaries and arterioles of the subcutaneous tissue and corium with a perivascular leukocytic infiltration, in cases of meningococcus septicemia. Injury to vessel walls allows an escape of red cells, thus accounting for the purpuric eruption.

Examination of the brain reveals only a congestion of the superficial vessels of the leptomeninges. This is true even in the cases of definitely proved meningococcal etiology.

Other pathological findings are merely such as would occur with an acute infection. Namely, Cloudy swelling of the parenchymatous viscera, acute splenic tumor and often a terminal pulmonary edema and congestion. A finding of perhaps more importance is the frequent occurrence of an enlarged thymus, prominence of the mesenteric lymph nodes, hyperplasia of Peyer's patches and solitary lymphoid follicles of the intestines. Sixteen cases in the literature were reported to have enlargement of Peyer's patches and lymph nodes. Ten specifically mention enlargement of the thymus. This thymolymphatic prominence has been pointed out by Rabinowitz²¹ and Bamatter¹⁵. The latter, in fact, believes it to be a factor of some importance in the pathogenesis of this disease, in view of recent work showing a definite correlation between status thymolymphaticus and adrenal hypoplasia.

ETIOLOGY

The determination of etiology presented difficulty to the early observers of this syndrome, perhaps because of its inherently fulminant character. Bacterial infection was early indicated as the probable cause, but a variety of organisms was found. Dudgeon²² found a *Staphylococcus aureus* in one case and a pneumococcus in another. Graham Little was able to demonstrate streptococci in sections of the skin. Waterhouse's case yielded a negative postmortem spinal fluid and blood culture, and he reported that in most cases cultures had been sterile. It is interesting to note that at the time of Friderichsen's report only 12 cases included data on blood culture. Of these, seven were sterile and the others included the variety of organisms mentioned above. McLagan and Cooke's¹² work, already referred to, is the first report to incriminate, definitely, the meningococcus. Herrick²³ has emphasized the fact that it is in the fulminating type of meningococcal infection that a striking purpura is most apt to be found. It is, moreover, in this type of case that adrenal hemorrhage is seen, rather than in the usual manifestations of meningococcus infection. It may be argued that the involvement of the skin and adrenal medulla, both of similar ectodermal origin, is an evidence of the ectodermal tropism of the meningococcus. The pneumococcus, likewise, possesses an ectodermal or epithelial tropism and, moreover, is capable of producing purpuric skin lesions as demonstrated by Mair²⁴ and Julianelle and Reimann²⁵.

Since McLagan and Cooke's report 21 cases, in the data of which definite statements as to etiology are included, have been added to the literature. Of these, 12, or 60 per cent, were due to meningococci. The others, constituting 40 per cent, either gave sterile cultures or growths of *Streptococcus hemolyticus* were obtained (Snelling and Erb). It is interesting to note that Bamatter, in 1934, found that only four bacteriological examinations had been done ante-mortem. Since then, three additional ante-mortem investigations have yielded meningococci. It seems, then, that the meningococcus is the most frequent, but not the only etiological agent found in this condition.

I should like to add to the total of 64 reported cases, two which recently occurred at the University Hospital.

CASE REPORTS

Case 1 C. H., white, female child, aged four years, admitted to the Pediatric service at the University Hospital on April 6, 1936, with a complaint of pain in the side, chills and vomiting. The past and family histories are completely non-contributory. The child had been entirely healthy until onset of the present illness. Two days prior to admission the child's mother had noticed a slight cough. On April 5, 1936, one day prior to admission, there was a slight nasal mucoid discharge. The child went to bed at 8 00 p.m. after having eaten a light supper and appeared quite well. At 11 00 p.m. she suddenly awakened with a cry and complained of pain on the right side of the chest. Soon afterward she experienced a chill, and vomiting occurred. The child remained restless, feverish and disoriented throughout the night. At 6 40 a.m. there was a generalized convulsion which lasted about five minutes. She was seen by a physician who advised immediate hospitalization. On the way to the hospital another convulsion occurred.

When seen in the hospital the child appeared extremely toxic, temperature 104° F., respirations rapid and shallow, and pulse averaging 165 to 180 per minute, characterized as thready and of poor volume. At this time over the chest could be seen numerous purpuric spots, limited to the right side and apparently distributed along the intercostal spaces. The child was lethargic, but her attention could be attracted. On physical examination the following important findings were noted: Several petechial hemorrhages in the conjunctivae, dilatation of the alae nasi with respiration, injection of the pharynx and fauces. Examination of the chest revealed it to be resonant, but on auscultation the breath sounds were broncho-vesicular and there were fairly numerous moist and crepitant râles at the bases, posteriorly. Aside from the tachycardia and feebleness of the pulse, the cardiovascular system was negative. The abdomen was distended, but showed no other changes. The reflexes were present and in the case of the patellar were even hyperactive. No cervical rigidity or other signs of meningeal irritation were present.

The blood picture, on admission, showed 3,000,000 red blood cells, hgb. 80 per cent, a total white count of 7,000 with 80 per cent polymorphonuclears and 20 per cent lymphocytes. Spinal fluid examination revealed a clear, colorless fluid containing 26 cells per cu. mm., predominantly polymorphonuclears. Blood culture, immediately after admission, showed a profuse growth of *Neisseria intracellularis*. Agglutination with polyvalent anti-meningococcus serum was markedly positive up to a dilution of 1:1560.

The child was put to bed immediately after admission and intranasal oxygen was started. In spite of sponges the temperature rose to 107.6° F. At the height of the

FIG 1 Low and high power photomicrographs of the adrenal (case 1), showing extensive hemorrhage and destruction of parenchyma

fever a macular, purpuric eruption appeared on the face, neck and lower extremities. Cyanosis of the hands, feet and back was quite pronounced. Respirations became slower and more labored. About one-half hour before death the child vomited about 200 c.c. of liquid black material, which gave a positive chemical reaction for blood. In spite of all medications death occurred at 5 30 p.m., April 6, 1936, approximately 18½ hours after onset.

An autopsy was performed two hours following death. The body was that of a well-developed and well-nourished child, showing a macular, petechial and purpuric eruption, most marked over the anterior chest. Numerous petechiae were seen in the bulbar conjunctivae. The mesenteric lymph nodes were prominent and had a reddish tint. The thymus was of normal size and presented no gross pathologic change. The lungs, liver, kidneys, heart, pancreas and gastrointestinal tract revealed no gross or microscopic lesions. The spleen was moderately enlarged and weighed 60 gm. The adrenals were of the usual size, but had a striking, deep, hemorrhagic color. On section gross hemorrhagic involvement of the cortex and medulla was present. Histological examination revealed diffuse hemorrhage throughout the entire adrenal substance with beginning necrosis of both the medullary and cortical tissue. Examination of the brain revealed congestion of the vessels of the leptomeninges, but no other gross or histological changes.

Case 2 The history and physical examination of this case are necessarily fragmentary since the child was brought to the accident room in a moribund condition and died within a few minutes after admission. The brief anamnesis was all that could be obtained from a distraught and hysterical parent. This is a white, female child, R. C., aged 2½ years, who became ill quite suddenly during the evening of July 7, 1936. Her illness was characterized by marked prostration, hyperpyrexia and several generalized convulsions. The patient was seen by a physician on the morning of July 8, 1936, at which time she was comatose. The skin of the face, neck, trunk and extremities was covered by a profuse, macular, petechial and purpuric eruption, which, in some places, was confluent. The individual lesions measured up to approximately 5 cm. in diameter. Immediate steps were taken to secure hospitalization, but as stated above, the patient was in a moribund state when first seen in the accident room. Death occurred at 2 00 p.m., July 8, 1936. The duration of illness, as closely as can be determined, was less than 24 hours.

An autopsy was performed one hour after death. External examination revealed a diffuse, macular and, in some places, petechial eruption, involving the face, neck, back, abdomen, chest and the upper and lower extremities. Although only slight rigor mortis was present and only a short time had elapsed since death one was struck by the diffuse cyanotic discoloration of skin, apart from the distinct eruption. The conjunctivae were injected, but presented no petechiae, nor were petechiae seen on any of the serous membranes of the body. There was moderate gaseous distention of the intestinal tract. The thymus was somewhat enlarged, weighing 30 gm., and there was prominence of the mesenteric lymph nodes which appeared somewhat reddened. Lymphoid hyperplasia was, likewise, noted in the Peyer's patches and solitary follicles of the ileum. The lungs, grossly and histologically, revealed evidence of edema and congestion. The heart, liver and kidneys showed no marked lesions aside from a moderate degree of cloudy swelling, compatible with any acute infection. The spleen was enlarged, weighing 65 gm. and histologically showed a typical acute splenic tumor. The adrenals, although of normal size and shape, exhibited a diffuse, deep red, hemorrhagic appearance, which completely obliterated all normal landmarks of cortex and medulla. Histologically there was extensive hemorrhage confined within the limits of the capsule of the adrenal. The densest collection involved the medulla and zona reticularis with apparently secondary involvement of the outer layers of the cortex. There was complete disruption and necrosis of all but a very

small outer shell of adrenaal tissue. In addition to fresh blood, collections of blood pigment could be seen scattered throughout the section. A careful search for organisms was made in sections stained by Goodpasture's method, but none were found.

The brain was examined by Dr. James G. Arnold, Jr., who found scattered petechial hemorrhages present, particularly in the region of the ventricular system. One early encephalitic focus was found in the thalamus. There was nothing specific in the findings to suggest a purulent meningitis, they were simply such as might be present in any septicemia.

Blood Culture postmortem blood culture revealed a pneumococcus, type 1

COMMENT

In view of the predominant meningococcal etiology, the infrequency with which these cases are seen is surprising. It appears to us, and to several other observers, notably Rabinowitz, Bamatter and Aegerter, that the thymolymphatic prominence is an important factor in the pathogenesis of this disease. To the 10 reports of thymic enlargement we add, in case 2, additional support in the form of a thymus, weighing 30 gm., in a 2½ year old child. The definite relationship between atrophy, or hypoplasia, of the adrenals and status thymolymphaticus is a well known fact. The assumption that the rarity of these cases is the result of the infrequent coincidence of these two factors can be proved only by further careful observations. Other constitutional and physiological factors have been mentioned, such as the marked vascularity of the adrenals in infants and the increased sensitivity of the suprarenal vessels to vasodilating toxins, but they seem untenable in view of the occurrence of cases in adults.

It is interesting to note, here, that even in cases of definitely proved meningococcal etiology, the leptomeninges have shown only slight involvement in the form of capillary congestion. This, of course, merely supports the well known occurrence of bacteremia preceding the usual manifestations of meningitis.

A hitherto unmentioned pathological finding is noted, also, in case 2, i. e., the occurrence of minute petechial hemorrhages in the white substance of the cerebral hemispheres, especially adjacent to the ventricular system. This, however, is believed to be nonspecific and merely in keeping with the finding of subserosal petechiae in the epicardium, pleura and peritoneum in this and other types of septicemia. It may, however, be of significance as the background for the coma and convulsions often seen in these cases.

The frequency of sterile blood cultures, even in recent reports, is deserving of consideration. Bamatter suggests as possible reasons phagocytosis by body cells, antibodies in the serum being carried over into the culture media, the organisms, though few in number, being especially virulent in their effect. Finally, the isolation of other organisms, such as the pneumococcus in one of our cases, necessitates some explanation. One may suggest an ectodermal tropism, similar in a way to that of the meningococcus, on the part of pneumococci.

SUMMARY

1 Two cases of the so-called Waterhouse-Friderichsen syndrome are reported

2 Review of the literature reveals a total of 64 cases, 70 per cent occurring in children below the age of two years

3 Twenty-one case reports mentioned bacteriological etiology, 60 per cent were meningococcal in origin. The remaining 40 per cent were due either to *Streptococcus hemolyticus* or the pneumococcus, or were reported sterile after careful examination

4 The outstanding pathological finding is bilateral adrenal hemorrhage, usually of a massive type

5 The clinical picture of a rapidly fulminating, septic course, associated with a striking purpura, is considered of sufficient definiteness to warrant consideration of this syndrome as a clinical entity

VARIATIONS IN RESPONSE TO THERAPY IN PERNICIOUS ANEMIA *

By L. MARY MOENCH, M D , *New York, N Y*

ADEQUATE treatment of pernicious anemia should result in the restoration of a normal blood picture and in the disappearance of those symptoms and signs which are not due to irreversible tissue changes. It is necessary to know the amount of potent factor required to bring the erythrocytes to normal and to maintain these cells at such a level. It is also important to determine whether, in spite of apparently adequate therapy, a significant fall in the red blood cell count may occur. If such a fall occurs we should like to know whether it is attended by other evidence of clinical relapse. A study of the records of the patients under active treatment in the Hematology Clinic of the New York Hospital was undertaken to see if information could be obtained which would throw some light upon these problems.

The total series of patients studied numbered 36, of this total, 33 patients had been given treatment for a sufficient period of time to elevate the red blood count to normal, and of these, 32 had been treated in the Clinic for periods of time that permit a satisfactory evaluation of data which might yield information about maintenance conditions. Of the group of 32 patients the average length of the maintenance period was 21 months, the shortest period being five, the longest 50 months. The preparations used in treatment were Lederle Liver Extract (3 c c of which were derived from 100 grams of liver), and an unconcentrated extract prepared in the laboratories of the New York Hospital, 10 c c of which were derived from 50 grams of liver. The latter preparation was given those patients who could not afford the cost of the commercial preparation. The amount of New York Hospital extract given was shown by experience to produce results comparable to those obtained by the highly refined commercial preparation. These preparations were given by intramuscular injection, the average amount consisting of a total monthly dose of material derived from 300 grams (Lederle) or from 200 grams (New York Hospital). The patients were seen in the Clinic at least once a month when counts were made and the patients questioned and examined. When the red blood cell count fell appreciably or the patient showed some subjective or objective evidence of relapse the amount of material was increased or was supplemented by whole liver or by Lextron †. As these patients were observed on their recurring visits, the impression was gained that the amount of liver given routinely

* Received for publication December 8, 1936

From the New York Hospital and the Department of Medicine, Cornell University Medical College.

† LEXTRON (Eli Lilly)-Liver Stomach Concentrate 0.455 gm, Ammonium Citrate (Green) 0.2 gm Adsorbed Vitamin B—0.016 gm

was yielding satisfactory results in most cases, and the counts (both individually and as regards the general trend) seemed up to the normal standards

A standard for erythrocyte values has been established from numerous studies of normal individuals. Wintrobe¹ has published an analysis of a number of such series from the literature as a result of which the average red blood cell values for men have been placed at 5.4 and for women at 4.8 million erythrocytes per cubic millimeter of blood. In his own series of normals (86 men and 101 women) the normal variation for men was found to lie between 4.9 and 5.98, and for women, between 4.44 and 5.60. In our pernicious anemia patients who were in remission the average count for the entire group of women (19) was 4.5 and for men (13) 4.83. It will be noted that these figures fall below the mean average of the normal group but lie within the limits of normal variation for women and just under the low normal for men. These averages are lowered by inclusion of several cases not satisfactorily controlled. If we consider the mean erythrocyte count of 4.44, given by Wintrobe, as the lower limit of normal variation for women, there were five patients in this group whose average counts lay below this figure, and of the men also five patients whose average remained below the lower figure for men. These patients are presented as cases 1, 21, 31, 23 and 36 (women) and 24, 14, 9, 12 and 25 (men). The lowest average in this group occurred in two women both with counts of 3.9, and of the men, two patients had average counts of 4.3. If these 10 cases are excluded from the series—the 10 records will be later presented in detail—it will be seen that the remaining 23 patients show erythrocyte averages that lie well within the range of normal values and they can be considered well controlled from a hematologic standpoint. Since these patients (70 per cent of the series) gave a satisfactory hematologic response to amounts of active principle which consisted on the average of potent factor derived from 300 grams of liver (Lederle) or from 200 grams (New York Hospital Extract) per month, they may be used for comparison with those subjects whose average counts failed to attain the normal. It will be of interest to compare the amount of active principle given to these latter individuals with the average used for the entire group and to see whether the disease under these presumably unfavorable conditions seemed to be clinically controlled or showed some evidence of activity.

CASES REFRACTORY TO TREATMENT AS DEMONSTRATED BY LOW RED BLOOD CELL COUNTS

As previously stated, the average total dose of material per month consisted of substance derived from 300 grams of liver (Lederle) or from 200 grams (New York Hospital). This quantity undoubtedly exceeds the minimum requirement for the average case. Murphy² was able to maintain a normal erythrocyte level, of from 4.5 to 5 million or over, with as little as 1 c.c. prepared from 100 grams (Lederle) given at intervals of about 21

days, and Stungis² with an average monthly total quantity of material from 80 grams (preparation not stated). It will be noted, therefore, that although amounts considerably in excess of that usually found effective were given, the average count of these patients fell below the optimal level. A brief summary of this group of "refractory" patients is presented to emphasize the amount of liver extract used, the hematologic response to treatment and the symptomatology as it appeared at the end of the maintenance period arbitrarily chosen for the purpose of the study.

Case 1 A woman, 40 years of age, gave a history of periods of exhaustion, glossitis and diarrhea with intermittent paresthesias of the hands and feet for five years. The erythrocyte count on admission was 148 million. The maximum reticulocyte response was 19 per cent on the sixth day, and the erythrocytes reached 46 million in the third month of treatment. This level was not held, and an average count of 39 million was maintained over a period of 23 months. During this time she received as an average total monthly intake, the material derived from 600 grams (Lederle extract) alternating with that from 200 grams (New York Hospital extract). Her general and neurological symptoms were entirely controlled, and there was no objective evidence of progress of the disease. She experienced periods of nervous irritability and stated that she would fly into a rage with little provocation. She would awaken at night obsessed with fear of she "knew not what."

Comment Except for periods of emotional instability this patient was free of symptoms.

Case 23 A woman, aged 30 years, with symptoms of vertigo and weakness for two months, showed an erythrocyte count on admission of 20 million. A reticulocyte peak of 14.9 per cent occurred on the fourth day of treatment, and an erythrocyte count of 45 million was obtained in five weeks with a total dose consisting of the material derived from 500 grams of liver (Lederle extract). The average amount of material given per month over a period of 15 months was that derived from 300 to 600 grams (Lederle extract) and the average erythrocyte level attained during this time was 42 million red blood cells. This patient also had exophthalmic goiter for which a subtotal thyroidectomy was done during her treatment for pernicious anemia.

Comment The general symptoms have disappeared and there has been no evidence of central nervous system involvement.

Case 31 A woman, 47 years of age, complained of weakness, glossitis and flatulence for four or five months. On admission the erythrocyte count was 28 million. The reticulocyte response to treatment could not be followed as the patient was ambulatory. The count reached the 45 million level after six weeks' treatment during which she received in all the material from 350 grams of liver (New York Hospital extract). During the following year the count averaged 40 million while receiving per month material derived from 300 to 600 grams (Lederle extract) alternating with New York Hospital extract derived from 200 grams. This patient has not experienced symptoms in spite of the relatively low count until within the past few weeks, when mild paresthesias were perceived similar to but less noticeable than those that had troubled her some years prior to treatment.

Comment The disease has been symptomatically controlled until within the past few weeks.

Case 21 A woman, 52 years of age, with an admission count of 3.7 million erythrocytes, was treated for 28 months after the red blood cell count had been stabilized, and during these months the average count was 4.2 million. The monthly intake consisted of the material derived from 300 to 600 grams of liver (Lederle extract) with intervals during which extract from 200 grams (New York Hospital extract) was used. This patient stated that the extreme weakness which she had experienced prior to treatment had entirely disappeared, and the paresthesias which had been severe had improved although they were still present and troublesome. Vibration sense on admission was reduced in both upper and lower extremities and was unchanged after a two year period of treatment. There was some loss of joint sense, and the heel to knee test was poorly performed. There was some impairment of cutaneous sensibility over the lateral halves of both legs and much mental depression and irritability. None of these features was altered during the maintenance period although the extreme mental confusion and lack of orientation present at the time of her admission to the hospital cleared following a few weeks of treatment.

Comment This must be considered an unsatisfactory result, both as regards subjective and some objective evidences of the disease. The blood reached 4.5 million erythrocytes at one time. Then the therapy was changed to ventriculin. The immediate response was good, but after return to liver extract the erythrocyte count dropped and remained below the desired level.

Case 36 A woman, aged 41, had been treated six months previously in the hospital, but because the count could not be maintained, she was readmitted with a count of 2.3 red blood cells. The maximum reticulocyte response of 17 per cent occurred on the eighth day, but the count never reached 4.5 million. Material from 3500 grams of liver was given during her month's stay in the hospital. During the 15 months following she has received amounts of material ranging from that derived from 200 grams (New York Hospital extract) to that from 400 grams (Lederle extract) within four week intervals. The erythrocyte level has averaged 3.9 million. With this relatively low level there have been no outspoken signs of the disease, and she has never shown evidence of central nervous system involvement. However, she has not felt in perfect health and has continued to tire easily.

Comment Although this patient was given somewhat more liver than the average patient, undoubtedly in view of her general symptoms of fatigue a larger amount should be given in an attempt to elevate the blood to a higher level. This patient was mentally depressed and undernourished. Whether these conditions had an indirect effect upon the production of erythrocytes is a matter for conjecture.

Case 24 A man, aged 36 years, was admitted with an initial count of 2.8 million red blood cells. The reticulocyte response was not obtained as the patient was ambulatory. The erythrocyte count rose slowly over a period of five months to a level of 4.5 million. This count was not maintained, however, and he continued to complain of flatulence and of vague gastrointestinal symptoms with much mental depression. The average count over a period of nine months was 4.3 million on a monthly total intake consisting of the material from 300 grams of liver (Lederle extract). The glossitis, which had been present prior to treatment, disappeared. The central nervous system remained objectively negative, and there were never any paresthesias. Following a change in his fortunes the gastrointestinal symptoms disappeared, and it

is possible that they were in part of functional origin, although the Graham-Cole roentgenogram of his gall-bladder showed the presence of adhesions

Comment Although this patient's blood count remained at a relatively low level, he obtained satisfactory symptomatic relief, and there was no apparent progress of his disease

Case 14 A man, aged 66, was under treatment for 15 months. His initial count was 1.4 million erythrocytes and the reticulocyte peak, occurring on the sixth day, was 30 per cent. There was a slow rise over a five month period during which he received material from 550 grams of liver (New York Hospital extract) in the first month, and in subsequent months that from 600 to 1200 grams (Lederle extract). Following the use of the Lederle extract from 1200 grams the erythrocyte count reached a level of 4.7 million, which, however, was not maintained with subsequent monthly doses of Lederle extract from 300 grams. The average count over a 12 month period was 4.3 million. In spite of this relatively low level he became symptom free at an early stage in his treatment, regained strength rapidly, and the diarrhea which had greatly troubled him disappeared. The paresthesias present intermittently for five years cleared entirely except on crossing one knee over the other when the pendent extremity became numb to a greater degree than he considered normal. No change, however, was observed in the hyperactive reflexes.

Comment This case is of interest because of the large amounts of liver necessary to raise the count temporarily to within normal limits, at which level it was not maintained with average amounts of liver. There was no evidence of progression of the disease and the patient was practically symptom free.

Case 10 A man, aged 60 years, stated that he had been troubled with weakness, exhaustion and paresthesias to a greater or lesser extent for three years. His erythrocyte count on admission was 1.9 million. The reticulocyte response rose to 38 per cent on the twelfth day, and in 11 weeks his erythrocyte count had risen to 4.5 million with the use of material from 600 grams of liver (Lederle extract). During the 32 months of treatment to date he received as an average monthly dose the material from 300 grams of liver (Lederle extract) alternating with New York Hospital extract from 200 grams of liver, and the level of his erythrocytes during this period was 4.6 million. The general symptoms were completely relieved, but the paresthesias persisted over the two year period of treatment and were described as a sensation of hot water on his finger tips and a band-like constriction around his knees. Vibration sense was reduced below the twelfth dorsal segment and absent over the knees, ankles and toes. Cutaneous sensibility was impaired below the twelfth dorsal segment. There was no improvement in the symptoms of central nervous system involvement during treatment, but, on the other hand, there was no progression of objective signs.

Comment An apparent arrest of moderately advanced subacute combined sclerosis with only fair hematologic response to treatment.

Case 12 A man, aged 84, gave a history of symptoms for nine months prior to his admission. During the first year of treatment his count averaged 4.1 million while being given the material derived from 500 to 600 grams of liver (Lederle extract) at monthly intervals. During the second year, the count averaged 3.6 million on extract from 600 grams of liver (Lederle extract) once a month. During the third and fourth years 4.4 and 4.6 million on extract from 600 to 800 grams of liver (Lederle) once a month. As supplementary treatment he was given six Lextron

capsules daily as well as whole liver in amounts approximating 230 grams daily. Although the amount of liver administered was large (at times he received extract from 300 grams twice weekly) the count was at no time above 5,000,000 red blood cells and the average for the total maintenance period falls below the normal as noted. His general response to this treatment was very satisfactory and his strength and sense of well-being were remarkable considering his advanced age. Incapacity from involvement of the central nervous system, however, progressed slowly; there was a gradual and progressive loss of vibration sense in the lower extremities, the paresthesias of the hands and the band sensation of the legs seemed at times more troublesome, the ataxia became more marked, the Romberg was persistently positive and the finer movements of the hands were performed with difficulty. The advance of these changes was so slow that it was scarcely perceptible to the patient who was able, in spite of his age, to carry on an active life as an actor in a federal project.

Comment It was impossible to control the progress of the disease in this aged man in spite of exceptionally large amounts of active principle.

Case 25 A man, aged 55, gave a history of symptoms referable to pernicious anemia for a year and a half prior to admission. The initial count was 3.2 million. The maximum reticulocyte count of 67 per cent occurred on the seventh day of treatment. There was a slow rise over a period of five months during which a total dosage consisting of the material derived from 3550 grams of liver was administered, 550 grams of which were extracted by the New York Hospital method and the remainder by Lederle. The average count of 4.6 million was maintained over a period of six months by the use of material from 600 grams of liver (Lederle extract) monthly, supplemented by a daily oral intake of 230 grams of whole liver and six Lextron capsules. During this time he became practically symptom free and stated with enthusiasm that he felt better than in many years. Paresthesias of a constrictive nature about the waist and thighs and numbness of his fingers disappeared within six months after his blood had reached the 4.5 million level, except as he repeatedly stated, when he smoked cigarettes, following which the paresthesias, especially in the legs, reappeared. Vibration sense was diminished in the lower extremities and did not return. The central nervous system was otherwise objectively negative.

Comment This case may be considered controlled although the erythrocytes have remained below the desired level.

Of these 10 patients whose erythrocyte counts did not measure up to the normal standard with therapy which is usually adequate, eight have apparently been fully controlled as far as symptoms and signs are concerned. In two the disease showed some evidence of activity. One of these latter showed slight amelioration of symptoms and the other evinced a slow progression of central nervous system changes. In this last case (case 12) it is possible that advanced age may have played a part in the resistance to treatment. As for the former (case 21) there was no objective evidence of advancing signs of the disease although the symptoms were only slightly improved by treatment. In commenting on case 21, it is only fair to point out that the same condition may exist in patients whose blood counts are at or above normal levels, as in case 29 which will be later presented in detail. This patient (case 29) had a normal red blood cell count and hemoglobin, although he had never received liver prior to admission. The symptoms likewise failed to respond to massive liver therapy although there was no ob-

jective evidence of progression. As regards the amount of liver given this refractory group of patients, it will be noted that none of these patients received less than the average amount of liver which served to maintain the blood of 70 per cent of the series at a normal level (Lederle extract from 300 grams of liver or New York Hospital extract from 200 grams of liver monthly), all of the women and three of the men received approximately twice the average amount and two patients received supplementary oral liver.

In contrast to the relatively large amount of active principle given these "refractory" patients, an occasional patient proved to be satisfactorily controlled from a hematologic as well as from a clinical standpoint on a much smaller amount of liver. The two cases which follow illustrate (a) the ease with which one patient was maintained on a small amount of liver (Lederle extract from 150 grams of liver) monthly and (b) in the second case, progressive improvement in the blood count on a constant amount of liver (Lederle extract from 300 grams, or New York Hospital extract from 100 grams) given over a period of three years. In the first case, since it was exceptional to obtain maintenance of a satisfactory count on such a small amount of material, the question arose as to whether the treatment might have coincided with a spontaneous remission. However, since the dose was not altered during a year's time and since Murphy obtained satisfactory results with equally small amounts of material it probably represents actual maintenance conditions.

Case 5 A woman, aged 55, gave a history of marked weakness, some dyspnea, sore tongue and periods of diarrhea. Paresthesias had not been present. On admission her erythrocyte count was 1.08 million. The maximum reticulocyte response of 33 per cent occurred on the eighth day, and the erythrocytes rose to 4.5 million in 13 weeks on a total intake consisting of the material from 2500 grams (New York Hospital extract from 1300 and Lederle extract from 1200). Thereafter her blood was maintained for one year to date at an average of 4.9 million red blood cells on material from 150 grams of liver (Lederle extract) at monthly intervals. Her symptoms cleared entirely and there were no objective signs of the disease.

Of interest also is the second case because the blood displayed an increasing rise of the erythrocyte level during the period of study (approximately three years) on a constant amount of liver, not exceeding the average monthly dose given the entire group (Lederle extract from 300 grams of liver). It would seem that a gradual storage of active principle may occur which yields a maximal hematopoietic effect only after some time has elapsed.

Case 4 A man, aged 59, sought medical attention because of extreme weakness and exhaustion. He had noticed transient paresthesias and stated that his sense of taste had become impaired—that all food "tastes and smells like rubber." His red blood cells on admission numbered 1.82 million, and the maximum reticulocyte response of 34 per cent occurred on the tenth day. The count rose to 5.1 million on material from 600 grams of liver (Lederle extract) in six weeks but thereafter dropped and remained at an average level of 4.5 million for six months on material from 300 grams of liver (Lederle extract) monthly. During the second six months the aver-

age count rose to 4.7 million, the following 10 months to 4.9 and during the 10 months to date it averaged 5.2 million. For a period of 20 months New York Hospital liver extract (derived from 100 grams of liver) was given at monthly intervals, during which time as well as during the time that the Lederle extract was given there was an approximate monthly increase of 30,000 erythrocytes.

The patient is entirely symptom free. His general strength is excellent and he states that his sense of smell has returned to normal. The paresthesias have practically disappeared. However, vibration sense remains impaired below the twelfth dorsal segment.

TIME REQUIRED FOR THE ERYTHROCYTE COUNT TO REACH 4,500,000 AND AMOUNTS OF LIVER USED

The group of 33 cases was analyzed to determine the length of time required and the amount of material used to bring the count to 4,500,000 red blood cells. Since some differences were observed that could not be entirely explained by the height of the initial count, an attempt was made to determine other factors, as for example the duration of the disease prior to treatment, which might be operating to delay the response to treatment. The estimated duration of the disease prior to treatment as dated from the first symptom noticed by the patient may be unreliable. In many instances the development of symptoms is so gradual that they may not be noticed until some unrelated event, such as an acute infectious disease, brings the symptoms to the patient's consciousness. Many patients, however, do offer a definite opinion as to when their symptoms began, and an attempt was made to correlate this with the time required to bring the count to normal. Some correlation will be noted. Of the 33 cases, 15 reached the 4.5 million level in two months or less. The average total amount of liver extract given was that derived from 670 grams (combined New York Hospital and Lederle extracts). The average initial count was 2.6 million erythrocytes. The duration of symptoms prior to treatment averaged 13.1 months. Of a second group requiring more than two but under three months to reach this level, there were 11 patients with an average initial count of 1.9 million. The average amount of material used in this group was that derived from 1072 grams (combined New York Hospital and Lederle extracts). The approximate duration of symptoms averaged 23.1 months.

A third group emerged from this analysis which was of considerable interest. This consisted of a number of patients who required more than three months for the erythrocyte count to reach the 4.5 million level. Many observers regard it as exceedingly unusual for the blood to fail to reach 5,000,000 within eight weeks, even with relatively small amounts of liver extract. Murphy found that 1 c.c. prepared from 100 grams of liver weekly was sufficient to raise the blood to the 5,000,000 level in eight weeks or less. In our group there were seven patients who required over three months to reach a count of 4,500,000 and to whom a minimum consisting of extract from 1600 grams and a maximum of extract from 6,600 grams of liver were

given. In these patients the average initial count was 2.9 million, and the slow rise is the more surprising in view of this high initial count. One patient in particular may be cited (case 36), who was given a total consisting of extract from 6,600 grams but whose count did not rise above 4.1 million in five months. In spite of this atypical response the diagnosis of pernicious anemia was retained as all other causes for her anemia had been excluded. Because of the special interest in this group of cases the details of these cases are summarized in the table. Other features in the clinical history or ex-

TABLE I
Cases Refractory to Treatment
(More than three months required for red blood cells to reach 4.5 million)

Case	Age	Duration of Symptoms (Months)	Initial Count	Time to reach 4.5m (Months)	Therapy (total grams)*	Remarks
12	84	9	3.6	9	5400	Senility
14	66	72	1.4	5	3860	Senility Frequent relapse in six years
24	36	12	2.8	5	2000	No CNS involvement
25	55	18	3.2	5	3000	Marked depression
27	68	72	3.9	4	1600	Chronic sinusitis Insufficient liver (?)
31	52	1—	3.7	4	900	Senility Malnutrition
36	41	1	2.3	5 to 4.1m	6600	Long history Insufficient liver (?) Marked depression (situational)

* Total of grams of liver, the extract from which (Lederle extract and New York Hospital extract) was administered

amination that were in any way unusual are enumerated in the column under the caption "remarks," although there is no experimental evidence that the rate of hematopoiesis is influenced by any of the factors mentioned.

It will be noted in the summary of the entire group that less than half of the patients showed a rise of erythrocytes to the 4.5 million level in less than two months. This result does not correspond with Murphy's experience, since all but two of his patients reached the 4.5 level in two months or less, and none failed to reach the 5 million level on amounts of extract between that derived from 500 to that from 1500 grams of liver (Lederle). The amount of liver extract used by our patients whose blood reached the 4.5 million level within two months was derived from 200 to 1500 grams of liver, but corresponding amounts failed to elevate the count of the remaining 18 of the 33 cases. Murphy states, "Failure of the blood to reach 5,000,000 or more within about eight weeks or less was usually due either to failure on the part of the patient to appear regularly for treatment or for blood counts at the proper intervals." Our patients reported for counts at weekly, bi-weekly or at the latest, monthly intervals so that it does not seem likely that

the erythrocyte rise to the expected point escaped detection, and in those with a slow rise, later counts served as a control for the earlier counts. All patients had been thoroughly investigated, the majority as pavilion patients in the hospital, before the diagnosis of pernicious anemia was accepted and active therapy instituted.

RESPONSE OF SYMPTOMS REFERABLE TO THE INVOLVEMENT OF THE NERVOUS SYSTEM

The most serious and persistent symptoms encountered in the routine care of the clinic patient with pernicious anemia are those that result from combined system disease or from peripheral neuritis. These may be the first to appear and often prove the most resistant to treatment. Neuropathologists are not in agreement as to whether a true peripheral neuritis exists as a basis for the paresthesias, although when these symptoms are mild and transient and tend to disappear with treatment it is customary to attribute them to a neuritis of the deficiency type. When, on the other hand, they persist in spite of intensive treatment and a normal blood picture, or slowly increase in severity, one cannot escape the conviction that they have their origin in a progressive involvement of the cord. Woltman,⁴ who has made an intensive study of the brain changes associated with pernicious anemia, in a personal communication has commented as follows on this point: "You have raised a question that has bothered me a great deal also, namely the source of the paresthesias. There is no question about the degeneration in the peripheral nerves described by Hamilton and Nixon⁵ but I am by no means certain that they always account for all the paresthesias these patients have. The progress of paresthesias associated with pernicious anemia in an upward direction until the lower portion of the trunk is included certainly suggests that they may also have their origin in the spinal cord as does the not infrequent failure to disappear more completely than they sometimes do on adequate treatment. The paresthesias often do disappear entirely, as might be expected in cases of degeneration of the peripheral nerves or where the spinal cord has not yet been too severely involved. That changes in the spinal cord may recede in some cases is proved by the occasional change of a positive Babinski sign to a negative one."

The subjective complaints from the paresthesias often seem out of proportion to the objective signs of cord involvement which may be so slight as to escape detection except by the most careful examination. For conclusive objective evidence not only of involvement, but especially as regards progression or regression, observations should be made at frequent intervals by the same examiner, as emphasized by Grinker and Kandel.⁶ Even under properly controlled conditions an evaluation of the findings is often extremely difficult. Vibration sense, two point discrimination, cutaneous sensibility are often unreliable in details, varying with the subjective interpretation of the patient not only from one examination to another but often

during the same examination. Objective signs offer more reliable criteria, and more significance may be attributed to such signs as a change from an ataxic to a normal gait, a decrease in sphincter disturbance, the disappearance of spasticity or a return to the normal of a Babinski reflex or of the Romberg sign.

Since the paresthesias often constitute the most troublesome symptoms and may persist after the general symptoms—the extreme exhaustion, the glossitis, the gastrointestinal manifestations,—have disappeared, they stand out in the patient's mind as an indication of whether or not the treatment is proving successful. Such symptoms consist not only of the familiar numbness and tingling but of various other abnormal sensations, among the most common of which is constriction, described as a band sensation around the body or the thighs or legs, occasionally around the head. Such expressions as "my head feels tight as a drum," "my chest seems in a vice," "legs feel as if they were bound and would burst" are common. An abnormal temperature sensation "as if my hands were in hot water" or "my feet feel as if I were walking on ice although they are not really cold" often is described. Extreme hyperesthesia occurs—"if the cat brushes against my legs it causes acute pain." Difficulty in walking may result from spasticity or from an altered position sense—"I am not sure where my feet are when I take a step." Defective sense of position gives rise also to such expressions as "I lose my legs in bed," "cannot sew because I do not feel the needle or know where it is going." Altered cutaneous sensibility in the feet is not uncommon, so that the patient feels that he is "walking on cotton," or "standing on a rubber ball," or the "hands feel as if they were stuffed." Occasionally actual pain is experienced, often in the legs or back. One patient described acute pain shooting from the soles of the feet up into the calves of the legs. Because of the severity of these symptoms various measures have been employed, but for the most part with little success. They have ranged from the use of large amounts of vitamins to various physical therapeutic measures. In one patient who complained of severe pain in the back roentgen-ray therapy was utilized with the hope that this method of treatment which is occasionally effective in certain types of intractable nerve pain might prove helpful in relieving the symptoms. No appreciable improvement was experienced. In those patients showing mild cerebral manifestations, such as depression, apprehension and irritability, a sedative often was beneficial. As a rule, marked cerebral disturbances, such as confusion, memory defects, paranoid tendencies or delusions, disappeared during the initial treatment.

Of the total series of 36 patients in this group, eight never experienced subjective symptoms other than transient paresthesias. Four were entirely relieved of such symptoms which varied in degree, 15 were considerably improved although not entirely free, in five the symptoms were unchanged and in three they became definitely worse. In one, although the paresthesias

were relieved, shooting pains had developed in the legs. As regards objective signs of the disease, as far as they could be determined by the clinic records, only one showed definite progression of the disease (a man aged 84 years), 17 were unchanged, in eight there was apparent improvement, and in 10 objective signs of involvement of the central nervous system had never been detected.

Not infrequently one encounters the report of subacute combined sclerosis not associated with the blood picture of pernicious anemia but apparently due to the same cause. If the etiologic factor is identical with that which produces the anemia, it is interesting to note that the severity of the central nervous system disease does not necessarily parallel the severity of the anemia. Nevertheless it is assumed that amounts of active principle which will elevate the blood to 5,000,000 or above will prevent the progression of central nervous system changes. When, however, the blood count has never been reduced, the count obviously cannot serve as an index of adequate treatment, and sufficient active principle is given, or more than necessary, to maintain the count at a high normal level, because of the empirical observation that if the blood is so maintained the central nervous system disease is held in control. Castle and Minot⁷ summarize our lack of knowledge of this phase of the disease as follows, "Until the hematopoietic principle of liver is isolated it will be impossible to find by therapeutic test whether it is also specific for the neural disturbance, or whether multiple factors, either intrinsic or extrinsic, are involved." The following case affords some evidence that progression of combined sclerosis may be held in abeyance by the administration of active principle. This patient has been under observation and treatment for three years. Although he has not been relieved of his symptoms—indeed he states that the paresthesias have become more severe—there has been no objective evidence of progression and the return to normal of the ankle jerks and of the Babinski reflex would indicate that some actual improvement had occurred.

Case 29 A man, aged 63, for a year and a half prior to admission had noticed great weakness, diminished power in his lower extremities and marked paresthesias of his hands and feet as well as a sense of constriction in his thighs. He dated the onset of his symptoms from an acute respiratory infection. Examination revealed markedly increased tendon reflexes with a positive Babinski. Position sense was very faulty and the Romberg sign was positive. Ataxia was marked, and he was unable to walk because of this and as a result of weakness. Vibration sense was greatly diminished in his lower extremities. He had never received liver or any other treatment. His hemoglobin estimation was 11.6 grams, red blood cells numbered 4,800,000, reticulocytes 12 per cent. The hematocrit reading was 46 vol per cent, and the volume index 1.1. There were some macrocytosis and anisocytosis. No free hydrochloric acid was demonstrated in his gastric contents with histamine stimulation. The spinal fluid did not impress the neurologist who saw him as of diagnostic significance, although the protein content was slightly increased and the colloidal gold curve appeared as 2222111111. There were 245 c.c. of residual urine, and the renal functional tests yielded normal values. The diagnosis was that of subacute combined sclerosis, and liver extract was given by intramuscular injection.

His general condition rapidly improved so that when he left the hospital he was able to walk without assistance. He has continued to feel very well generally but his paresthesias have persisted as well as the spastic gait and some degree of ataxia. He has received material from 600 grams of liver (Lederle extract) at monthly intervals as well as six Lextron capsules and whole liver daily (approximately 230 grams). Large amounts of vitamin B have been included in his diet. His erythrocytes over a period of 19 months have been maintained at an average count of 5,000,000. The sense of tightness, coldness and numbness of his hands has persisted, but a recent neurological examination, although unchanged in other respects, reveals that his Babinski reflex has returned to the plantar response and that the ankle jerk is of normal amplitude.

DISCUSSION

This study of the response of 32 patients with pernicious anemia to definite amounts of potent factor brings out several points of interest. It was thought on the basis of the satisfactory response of the majority of patients, as well as on the basis of the experience of other workers, that the average amount of material used (Lederle extract of 300 grams of liver or New York Hospital extract of 200 grams of liver per month) was ample, and indeed, in excess of what was required for adequate maintenance of the blood at normal erythrocyte levels. It was a surprise, therefore, to find that approximately one-third of the patients of this small series showed average red blood cell counts below the standard of normal. The majority of these "refractory" cases (eight of the ten) were given approximately twice the amount of material received by the other 22 patients who showed a "normal" response (an average of Lederle extract from 600 grams as against that from 300 grams of liver per month) as well as in several instances, supplementary liver by mouth in an amount, in itself, often found sufficient to maintain the average patient. It must therefore be concluded, since this unequal response occurs in a fairly large number of patients, that each patient with pernicious anemia must be managed as a separate problem and the dose individualized on the basis of the trend of the erythrocyte count averaged over stated intervals of time. The fact that the disease in eight of these ten "refractory" patients with low average erythrocyte values was controlled from the standpoint of signs and symptoms would make it appear that for some individuals a slightly substandard level of the erythrocyte count under treatment is not inconsistent with a satisfactory state of health. Nevertheless, the low level of the erythrocytes should be recognized and every effort made to elevate and stabilize the blood at a higher level. The possibility of relapse in these patients with severe damage to the nervous system, even when apparently under control, should never be forgotten. In our series, fortunately, no such serious relapse has occurred.

A second point of interest developing from the study consisted in the time required to bring the initial count to the minimum normal level. Although the majority of the group reached this minimum level within three months, and 15 within two months, in general the time required was in

excess of that reported by Murphy, who used corresponding amounts of material. In seven patients of our series even longer periods of time than three months elapsed before the red blood cells reached 4.5 million. Although, again, the amount of material was the same or more than that given the majority of the group and the initial count in several instances was not low, the blood of these individuals rose more slowly than it did in other instances where the initial count was considerably lower. These patients had been carefully studied and the diagnosis satisfactorily established, in several the pernicious anemia had been recognized and treated some years previously, but they were in relapse when the treatment which forms the basis for this study was begun. No satisfactory explanation can be offered for the atypical response of these patients, but many of them were additionally handicapped by some outstanding condition other than the pernicious anemia, as for example, a continuous depressive state arising from an unfortunate domestic or financial situation or by malnutrition or senility. Whether such conditions do actually influence the rate of hematopoiesis is a matter for conjecture. Whatever the cause for these retarded responses, it would seem that no unqualified prediction can be made as to the length of time necessary to bring the count to normal on the basis of the level of the initial count or as estimated by the response of the average patient.

It would seem also that the effect of treatment upon the neurological aspects of the disease cannot be predicted. Senility, in one case in this series, in the presence of a fairly well elevated and sustained erythrocyte level, seemed responsible for the unsatisfactory result in controlling the central nervous system disease. The extent of central nervous system involvement may not parallel the red blood cell count. Several patients who had had repeated hematologic relapses did not show evidence of neural disturbance, whereas the most advanced case of combined sclerosis in the series had never been anemic. The difficulty of following the course of the combined system disease makes it imperative that careful, detailed and frequent neurological examinations be made and that maximal amounts of potent material be given these patients regardless of the height of the red blood cell count.

Finally, this study demonstrates that although the more concentrated material is more satisfactory for use because of its greater freedom from unpleasant reactions, it is not equal in potency to the unrefined preparation. Whereas material from 100 or 200 grams of liver represented in the unrefined preparation controlled the average case, an amount of concentrated preparation derived from 300 grams of liver was required for equally good results. Potent factor undoubtedly is lost in refining and in concentrating the material, and the amount available in the various preparations cannot, therefore, be measured accurately by the weight in grams from which the material was derived. In view of this variation in potency which depends upon technical methods of extraction and refinement, it is advisable to record not only the weight in grams represented by the preparation, but the specific brand employed.

CONCLUSIONS

1 The average red blood cell count of 32 patients with pernicious anemia was 4.5 million for women and 4.83 million for men after hematopoiesis had been stabilized by treatment. The average amount of material used was Lederle extract derived from 300 grams of liver or New York Hospital extract from 200 grams per month.

2 Ten of the 32 patients showed erythrocyte values below normal standards although active principle much in excess of what was adequate to control the average case was given. However, in eight of these ten cases the disease appeared to be clinically controlled.

3 The length of time required to bring the blood count to 4,500,000 was two months or less in 15 patients and between two and three months in 11. The initial count of those requiring two months or less was 2.6 million, of those requiring between two and three months the initial count was 1.9 million. Seven patients required more than three months to bring their count to normal. The poor general condition of these patients, due to various causes other than pernicious anemia, may have had a depressing effect upon the rate of hematopoiesis.

4 Of the total series of 36 patients only eight had never experienced symptoms of peripheral or central nervous system involvement. Following treatment, of 28 who experienced symptoms, four were entirely relieved, 15 were improved, in five there was no change and in three they became worse. In one the result was indeterminate. It will be seen, therefore, that although the majority of patients are benefited by treatment, no absolute prediction as to relief of symptoms can be made.

5 In spite of intensive treatment one patient showed progression of objective signs of central nervous system involvement. In 17 the signs were unchanged, in eight there was apparent improvement. In 10 patients there were no objective signs of neural disturbance.

6 Although patients may be free of signs and symptoms of pernicious anemia with average counts slightly below the normal, the fact that two patients with such levels showed evidence of beginning relapse indicates that a continued effort should be made to elevate and maintain the blood at a high level.

ARACHNODACTYLY AND STATUS DYSRAPHICUS, A REVIEW *

By RALPH H PINO, M D , EDMOND L COOPER, M D , and STEFAN
VAN WIEN, M D , *Detroit, Michigan*

PART I ARACHNODACTYLY

THE clinical picture of arachnodactyly as described by Marfan is so characteristic that one having it in mind could hardly fail to recognize it. Since the original description little has been added, there have, however, been an increasing number of case reports in recent years. We have been able to find but 13 reports of the disease in the English-speaking literature since 1903 and of these only three came from this country. It becomes apparent then that the condition is relatively unknown on this continent and it is equally true that the diagnosis will be made more often as our familiarity with it increases. Lloyd¹ gave in his recent article such an excellent résumé of the subject that this paper would hardly be justified were it not for the fact that an entirely new significance has attached itself to the condition through a new idea of Passow. This will be reviewed in the second half of this paper.

The essential feature of arachnodactyly is the striking length and slenderness of the extremities, especially of the hands and feet. To this is added the invariable accompaniment of other congenital defects such as cardiac or pulmonary anomalies, webbed fingers, highly arched palate, muscular dystrophy, spurring of the os calcis, and ectopia lentis. The condition apparently has its onset during intra-uterine life since in the majority of cases the typical thinness of the extremities is noted at birth. There does not seem to be a predilection for any particular sex. Weve² in 1931 found that of 82 cases reported to that time, 40 were females and 42 males. Most of the patients (about 50 per cent) are below the age of ten. However, Weve found 20 cases between 10 and 20 years of age. Two of Weve's cases were 40 and 62 years old, respectively, and Omond's case was forty-seven.

The first description of the syndrome came in 1896 by Marfan³ who gave it the name "delichostenomelia". He also used the exceedingly apt term "Spider Feet" because of the likeness of the narrow fingers and toes to spider legs. In 1902 Mercy and Babonneix⁴ suggested the name "hyperchondrioplasia". Achard⁵ called the condition "arachnodactyly" and this term has been accorded more frequent use than the others. Weve felt that all these terms expressed only part of the clinical picture or were prejudiced concerning the underlying pathology. He believed "congenital mesodermal dystrophy" a better term but preferred simply to use "Marfan's syndrome".

CASE REPORTS

Case 1 R M, a boy, aged six, had poor vision all his life. It was impossible to ascertain the vision in the usual way, due to his poor mentality, but it was evident from the way he used his eyes that he had very little sight. He was a tall slender child. The extremities were slender and the fingers and toes unusually long. There was webbing of the fingers. The muscles were poorly developed and this added to his appearance of thinness. The skull was dolichocephalic with prominent forehead and flattened occiput. The palate was highly arched. There was moderate kyphosis and moderate left scoliosis of the thoracic spine. The scapulae were winged. The thorax was of the asthenic type, flat and narrow. There was no deformity of the thorax, no acrocyanosis, no deformity of the feet or spurring of the os calcis. The nipples were symmetrical.

There was a dislocation of the lens in each eye downward and to the left. The pupil was small but reacted promptly to light and dilated well with mydriatics. The lenses were hazy and dotted with punctate opacities. The iris, O U, was tremulous. Cooperation was very poor but we were able to determine retinoscopically that the eyes were approximately 20 diopters hyperopic. At later examinations we noted that the lenses seemed to change position rather easily. There was no indication of heterochromia or Horner's syndrome. The boy was obviously defective mentally and a psychological examination was made by Dr. M. B. Weiner who concluded that there was cerebral maldevelopment. A considerable improvement in the boy's mental reactions was noted after he had worn 15.00 D spheres before each eye for several weeks.

Case 2 G K, a boy, aged five years, had always held things close to his eyes in order to see them. This patient was seen only once and our examination was incomplete. We are indebted to Dr. D. M. Stiefel for additional data. His complaint was that he tired easily when standing or walking, and that he had poor vision. He complained also of his legs and feet hurting. The most striking feature was the general hypotonicity of his skeletal musculature. This was exemplified by his great weakness and by the hyperextensibility of his wrists, ankles, elbows and hips. His hands and feet were unusually long and slender, and the fingers and toes were thin and tapering. The external ears showed a deficiency of the cartilage and deformity of the helix. The palate was highly arched. The skull was dolichocephalic. The scapulae were winged and the spine showed moderate scoliosis. There was a definite lack of subcutaneous fat which added to his wasted appearance. According to Dr. Stiefel the boy had a congenital heart defect.

Examination of the eyes showed bilateral iridodonesis. The pupils were small and responded poorly to homatropine. The lens on each side was luxated temporally. The fundus details could not be seen, and retinoscopy was difficult. Vision was 20/200 in each eye and was not improved with lenses, although the retinoscopy suggested a high hyperopia. The patient was not seen again and no further examination was made.

Case 3 Mrs. F B, a woman aged 37 years, had high myopia and dislocation of the lens in each eye, and detachment of the retina in the left eye. The patient was an exceptionally thin tall woman and her arms and legs were unusually long and slender, a fact which had been noticed shortly after her birth. The slenderness of the limbs was most marked distally and the fingers were typically "spider fingers" of the type seen in arachnodactyly. The phalanges were most involved. The skull was long and narrow. The hard palate was highly arched. The thorax was narrow, flat, and tapered toward the waist. There were no deformities. The scapulae were winged markedly. There was slight scoliosis of the dorsal and lumbar spine. The breasts were symmetrical and equal in size. Auscultation revealed a loud blowing systolic murmur at the cardiac apex. Her feet were unusually long and she stated when she bought shoes the salesman always mentioned the fact. There was no spurring of the

os calcis There was a noticeable lack of subcutaneous fat over the body The hands and feet were moist and warm All the joints showed hyperflexibility Roentgenograms of the hands and feet showed normal bone structure but the phalanges and metacarpals and metatarsals were slender and tapering The patient's father was not seen but he was said to be very tall and thin with long hands and feet He was said to have become blind "from glaucoma"

Vision O U equalled perception of light Projection of light was excellent with the right eye but very poor especially in the lower field, with the left eye In the right eye the anterior chamber was deep and the iris tremulous The pupil reacted well to light but did not respond well to a mydriatic The lens was densely white and opaque, and trembled with movement of the eye The direction of its dislocation was not ascertained since the pupil did not dilate well and a slit lamp examination could not be made In the left eye the anterior chamber was deep and there was iridodonesis The pupillary reaction was normal but its response to mydriatics was sluggish The pupil was aphakic The lens could be seen with the ophthalmoscope, lying in the vitreous below The retina above was detached, the detachment involving the upper half of the fundus and extending downward covering the macula There was no heterochromia or Horner's syndrome in either eye

Case 4 E T, a boy of 20, had poor vision all his life, with $+8.00 +3.00 \times 120$ V O D = $6/30$, $+6.00 +3.00 \times 90$ V O S = $6/30$ but could not be improved He showed bilateral dislocation of the lens, iridodonesis, and sluggish response of the pupils to mydriatics The lens O D became dislocated into the anterior chamber and was removed but vision could still not be improved

The fingers were long, thin and tapering and the arms were long The span of his extended arms was four inches greater than his body length The palate was highly arched He showed no deformity of the thorax and there was no evidence of any heart lesion The feet were long with long toes No spurring of the os calcis The muscles were well developed

Shortly after the lens O D was removed he suffered a skull fracture in an automobile accident At this time he developed detachment of the retina O D Since that time he has been operated on several times elsewhere for meningeal adhesions, to relieve epileptic attacks

Case 5 L T, a girl nine years old, sister of case 4, showed a bilateral dislocation of the lens downward The pupils did not dilate widely after instillation of homatropine There was iridodonesis O U The fundi were negative Vision O D = CF at 6 ft and O S = CF at 3 ft A $+10.00$ D^s each eye brought the vision up to 20/200 but it could not be further improved The hands were rather gracile with tapering fingers The feet were not unusually large The palate was rather highly arched The scapulae were winged and she showed an indentation near the lower part of the sternum suggestive of funnel chest There was slight scoliosis No evidence of heart disease, no deformities of the ears, no spurring of the calcaneus The muscular system was not abnormal

The mother of these two patients also had subluxation of the lens but showed no other evidence of the disease

Relatively few cases of arachnodactyly were reported in the early years following the first description Rietschel⁶ in 1917 found nine cases in the literature and in 1928 Carrau⁷ found but twenty Weve added 23 of his own cases in 1931 to the 60 previously reported Twenty-two additional cases have appeared since 1931 Arachnodactyly is definitely familial In the early cases this was not noted but more recently it has been found that practically all patients have other members of the family exhibiting char-

acteristics of the disease Lloyd¹ reported five cases in a family of six, King⁸ described three cases in one family, and Viallefont and Temple⁹ presented four members of one family with the condition Weve's 23 cases belonged to six different families, in each of which more than one member was involved

The etiology is not known Some authors believe it is an endocrine disorder, placing greatest importance on the pituitary gland Many of the essentials of the condition such as the long jaw, the long limbs, the hypertrophied ears, lend support to this idea, but the thinness of the bones is in direct opposition to it One author expressed the opinion that dysfunction of the pituitary caused acromegaly in adults, gigantism in infants, and arachnodactyly in fetuses Young discredits the pituitary theory since with few exceptions the onset takes place in intra-uterine life It has been stated that disorders of the endocrines cannot affect the fetus because of compensation by the mother It might be assumed that since the condition is definitely familial, derangements of the maternal glands might be a factor, but in most cases not all the offspring in a family are involved In cases where roentgenograms have been taken of the skull, the sella has not been found unusual The co-existence of so many varied signs is against the possibility of a pituitary fault¹⁰

The only other endocrine gland upon which the blame might be placed is the parathyroid It might be thought possible that the skeletal anomalies of the condition are due to a disturbance of calcium metabolism However, no evidence of such a pathogenesis was found in any of the cases in the literature

Several authors have likened arachnodactyly to mongolism, apparently because a few cases were reported with narrow palpebral fissures This idea is not acceptable, especially in view of the truth that the great majority of cases are of normal mentality

The condition is similar in some respects to congenital muscular dystrophy and it is true that the two must be closely allied In true congenital muscular dystrophy, however, there are rarely other congenital anomalies Young reported that in arachnodactyly the muscular electrical response was fairly normal, as opposed to the poor response in muscular dystrophy The typical case of primary muscular dystrophy begins in youth and is progressive, progress of the dystrophy in arachnodactyly has never been reported

The most popular conception of the pathogenesis is that there is a selective dystrophy of the mesodermal tissue On this basis Weve explained the involvement of the bones, tendons, ligaments, muscles, connective tissues, fat, heart, and blood vessels Other authors have recognized this explanation but felt that the idea of mesodermal dystrophy did not satisfactorily explain the involvement of other tissues which are not mesodermal in origin Kallius¹¹ felt that mesoderm, ectoderm, and entoderm were all involved As we will point out later, it is possible to explain all the findings on the basis of mesodermal maldevelopment

Piper and Irvine-Jones¹² expressed a more general conception of the etiology. They felt that a disease entity with so many and varied manifestations must be due to pathologic defects of the germ plasm originating in embryonic life when dependence on the maternal organism is complete. The hereditary nature of the disease is clinically undisputed and Weve feels that whatever the direct cause may be there is a hereditary factor.

As to the symptoms we find the extremities long and slender. The involvement increases distally and the phalanges and metatarsals and metacarpals are unusually long and thin and tapering.

Roentgenograms show the unusual thinness and slenderness of the long bones of the hands and feet, but otherwise are usually negative. In most reports the bony structure has been recorded as normal, although a few observers have noted an increased rarefaction and decalcification. The length of the long bones of the arms and legs is not only increased as compared to that in normal persons but there is also a relative increase in proportion to the length of the trunk. Webbing of the fingers is often present and acrocyanosis of the extremities has been reported frequently. The muscular development of the whole body seems to be deficient, the general muscular weakness sometimes being so great that it has been compared with that of amyotonia congenita and congenital muscular dystrophy. Most authors find kyphoscoliosis which increases as the patients grow and is due to the great muscular weakness rather than to any changes in the bony spine. Laxity of the joint ligaments is frequent, most patients exhibit hyper-extensibility of the joints, and dislocations are not unusual. Flexion contractures are due to contractions of the tendons and occur most often in the fingers. The thorax is usually of the asthenic type, flat, narrow and funnel-shaped, with delicate ribs. The scapulae are winged. The skull in most cases is dolichocephalic, although Piper and Irvine-Jones reported a case in which the skull was brachycephalic. The ears may show abnormalities in size or shape of the lobes. Usually the bony palate is highly arched. The calcaneus is occasionally spurred.

The occurrence of congenital anomalies of the heart and lungs seems not to be unusual. Two cases have come to necropsy. Boeiger's case¹³ showed a patent foramen ovale, and only two lobes in the right lung. In Piper and Irvine-Jones' case congenital lesions of the heart and failure of normal divisions of the lungs into lobes was found. Besides these cases, others^{10,13,14,15,16} showed clinical evidence of heart disease. Also in this regard it is interesting to note that several reported cases have died of pneumonia.

The ocular signs in arachnodactyly are most interesting and form a definite part of the clinical picture. The most frequent finding is the congenital dislocation of the crystalline lens. Weve found this defect in 25 cases in 1931. In our review of 105 cases in the literature it has appeared 45 times although possibly some of the cases are repetitions. Weve felt after thorough study that Pfaundler's case¹⁴ was identical with Boeiger's first

case,¹⁷ and that Cameron's case¹⁷ had previously been reported by Ormond and Williams¹⁸. It is also possible that Fleischer's¹⁹ and Thaden's²⁰ cases were identical. In our review we ignored these possibilities and considered all reported cases as distinct. The dislocation is usually bilateral and is always congenital though it may not be noticed for years after birth. The lens may be found luxated in any direction. Two cases (Thaden and Weve) have been noted where the luxation was completely into the vitreous and one of our own cases was found in this serious state. Others have reported a dislocation into the anterior chamber and this complication occurred in one of our own cases also. The incidence of ectopia lentis in arachnodactyly is probably considerably higher than 50 per cent. In the earlier cases the defect was not looked for and in other cases the eyes were not mentioned. In only 14 cases were the eyes reported as being normal and in some of these the recorder mentioned that the pupil did not respond well to mydriatics and a good intra-ocular examination was therefore impossible. A few authors^{2, 19, 20, 21} have noted that the lens is almost always reduced in size. King noticed a coloboma of the lens in two cases and Weve also mentioned the occurrence of this defect.

The pupil is often small and sometimes ectopic. The iris shows a sluggish response to the instillation of mydriatics. Doubtless this is due to maldevelopment of the dilator pupillae muscle. Iridodonesis is present in cases showing ectopia of the lens. Paralysis of accommodation has been reported by Weve and pupillary membrane remnants are found fairly frequently.

Other ocular signs in arachnodactyly are not consistently present. Although in some cases the refractive findings were not recorded it seems that most of the patients were myopic, sometimes the myopia being as high as 60 diopters (Weve). Boerger's first case showed a myopia of 16 and 20 diopters in the right and left eye respectively. Cameron, Ormond and Williams, Thaden, and de Hass²² reported cases with high myopia. In contrast to this, Bier's case²³ (in which there was no luxation of the lenses) showed a hyperopia of 9 diopters in each eye and Padovani's case²⁴ and several of Weve's were hyperopic. The refractive error cannot be given too great consideration in any case, however, since it may often be influenced by the abnormal position of the lens. Piper and Irvine-Jones recorded the occurrence of short lower lids in their patients. Nystagmus has been frequently mentioned and is probably due to the poor vision which most of these patients have. Other ocular signs such as nystagmus, fundus lesions, and megalophthalmos which have been mentioned, probably do not occur with greater frequency than in other groups of patients. Usually the orbits are large and there is a small amount of orbit fat, producing a sunken appearance of the eyes, which together with the long, thin face gives the patient an aged look and an appearance of suffering.

If any ocular manifestations throw light upon the etiology it must be

the ectopia lentis, since this occurs more often than other ocular defects. As noted above, the most generally accepted theory of the arachnodactyly is that the disease is due to a selective mesodermal dystrophy. The theory has been rejected by some investigators, however, since there are tissues involved (lens, zonular fibers, and iris) which are not mesodermal in origin. It can, however, be shown that the ocular defects in arachnodactyly may be explained on the basis of a mesodermal maldevelopment. There are two ways in which this may be done.

It is supposed by Treacher Collins²⁰ that the fibers of the suspensory ligament of the lens are originally cellular adhesions between the lens and ciliary processes, and that as the eye grows these stretch and develop into fibers. Dislocation of the lens could then be due to defective development of the suspensory ligaments in the third or fourth month of fetal life. If the adhesions are weak or absent in one part of the circumference of the lens, then the fibers opposite, instead of stretching will pull the lens in that direction. If the suspensory fibers are absent they will not be seen in the pupillary space attaching to the free border of the lens. According to Ida Mann²⁶ "the main factor in the production of absence or weakness of the suspensory ligaments appears to be a persistence for an abnormally long time of one, several or all of the vessels which usually connect the *circulus arteriosus iridis major* with terminal branches of the hyaloid artery around the edge of the optic cup. These vessels appear at the fifth week and begin to disappear at the middle of the third month of embryonic life. It appears then that such a defect as coloboma, or weakness of, the zonular fibers is due to causes arising in the second or third month—are remote from endocrine causation—and are developmental anomalies." It is seen from this that congenital dislocation of the lens can be explained by an anomaly of the embryonic vascular system, a mesodermal derivative. There are cases of arachnodactyly reported which showed ectopia lentis, in which the zonular fibers could be seen in the pupillary space attaching to the border of the lens. In these cases the ectopia lentis was obviously not due to absence of the zonular fibers but it could have been due to weakness of them. Moehlig is in agreement with this idea. He says, "the lens, while it is ectodermal in origin, could readily be affected by the mesodermal supportive tissues being weakened"³²

Perhaps a better way to explain the ocular defects was mentioned by Weve. He expressed the opinion that the dislocation of the lens is not due to a defect of the zonular fibers but rather to the small size and spherical shape of the lens. Since in many reported cases the zonular fibers were normal, this idea is acceptable. Passow pointed out that this microphakia could be a manifestation of a general mesodermal dystrophy. We know that the embryonic lens is surrounded by a rich vascular membrane, the *tunica vascularis lentis*, the anterior part of which is the pupillary membrane. The arteries of this tunic, as well as those of the iris, originate from the

long posterior ciliary arteries and anastomose with branches of the hyaloid artery. Hence it is conceivable that any dystrophy of the mesoderm in embryonic life could cause dystrophic changes in the *tunica vascularis lentis* (a mesodermal derivative) and so to the lens and the iris.

We have suggested here a theory of the causation of arachnodactyly which explains all the usual findings in the disease. The theory is not new; we have only endeavored to adapt it to the whole picture. A brief summary of the salient features of the literature on the subject and reports of five cases are also presented.

PART II STATUS DYSRAPHICUS AND ITS RELATION TO ARACHNODACTYLY

New significance has recently been attached to arachnodactyly by Passow²⁷. He considers arachnodactyly as identical or closely related to status dysraphicus, or "microform of syringomyelia," basing his belief on the similarity of the signs and symptoms of the two conditions. The entity of status dysraphicus being practically unknown in the American literature it seems necessary to give here a brief outline of the condition before discussing Passow's idea of its similarity to arachnodactyly.

The first suggestion that faulty closure of the neural tube (spinal dysraphy) might be an etiological factor in many of the hereditary neurological diseases was made by Henneberg, who demonstrated that in syringomyelia the spongioblastomas are united at the spinal raphe. He felt also that syringomyelia was a dystrophy of the spinal cord.

Syringomyelia consists in the proliferation of glial cells in the central region about the central canal of the spinal cord and medulla. This central gliosis characteristically breaks down into a cystic cavity. It is believed (Henneberg) that the gliosis arises from embryonic cell rests in the spinal cord, such cell rests being present because of faulty closure of the neural tube. Hence the term "dysraphy."

Following the recognition that syringomyelia is a dysraphy of the spinal cord Bremer²⁸ searched in patients with syringomyelia and in their families for developmental anomalies which would seem to result from a spinal dysraphy. He found a considerable number. There was a preponderance of the span of the extended arms over the body length. One of the most characteristic signs was the funnel chest and almost invariably associated with this defect he found acrocyanosis. The hands were usually moist and cold. Further there was frequently a kyphoscoliosis which might be due either to trophic or muscular disturbances. Winged scapulae and webbed fingers were of more than occasional occurrence. Another frequent and quite typical sign was a difference in the mammae, one mamma being smaller than the other and the mammilla showing less pigmentation. Finally there was spina bifida often associated with enuresis nocturna, anomalies of the ears, highly arched palate, and other signs usually referred to as stigmata of degeneration.

Bremer found these signs not only in cases of typical syringomyelia, but also in quite a number of "normal" people, and, whenever he found one of these symptoms there was always an accumulation of others belonging to the same group. None of these cases could be diagnosed as true syringomyelia though most of them showed some disturbances of pain and temperature sensation, and quite frequently some anomalies in the muscular system. But the characteristic symptom of syringomyelia, the progression, was absent in all of them. On examining other members of the family, typical syringomyelia was found in several instances, and almost every member of the family showed some of the symptoms described above. All these facts led Bremer to assume that there is a well defined syndrome that is definitely hereditary in character and that forms a continuous line from the normal individual to the definitely pronounced case of syringomyelia.

Since most of the structures involved, the sternum, the breasts, the spine and spinal muscles, the palate, and the spinal cord are midline structures he calls this syndrome "status dysraphicus" believing them to be due to faulty formation of the spinal raphe.

It was of course difficult to draw any conclusions as to the pathological changes that took place in the spinal cord of these patients, since they were of no serious nature and did not come frequently to autopsy. Therefore Bremer²⁹ followed all the cases which came to autopsy in the Pathological Institute in the University of Munich for some time and picked out those which showed any suggestive sign of status dysraphicus. He examined four cases, three of which showed increased glial tissue in an area which lay behind the central canal but did not reach the posterior horns. The difference between these and normal sections of the cord was not absolutely significant, only a few glial cells and mostly fibers being seen. The fourth case showed hydromyelia of the spinal cord. The changes were mostly in the cervical portion, few alterations being observable in the lumbar region. The most significant feature was a proliferation of the ependyma in the central canal. Examining relatives of these cases, in each particular family a few members could be found who revealed the typical picture of status dysraphicus.

The clinical picture of status dysraphicus was first brought to the attention of the ophthalmologist when Passow²⁷ published his classical studies in 1933. In addition to mentioning the general symptoms of status dysraphicus described by Bremer, he noted also the frequent occurrence of Horner's syndrome and heterochromia iridis. In 50 patients with Horner's syndrome and heterochromia he found signs of status dysraphicus in 80 per cent. Later he added more cases and in the whole series found signs of status dysraphicus in an even higher percentage. Anomalies of the sternum, especially funnel thorax, were common. Kyphoscoliosis, winged scapulae, and webbed fingers occurred frequently, often together. In most patients the span of the extended arms was greater than the body length. Differences in the size and position of the breasts were noted.

In fairness to the facts it should be mentioned that Horner's syndrome and heterochromia, while being found not infrequently in status dysraphicus do not occur as often as it may seem from reading this review. In most textbooks Horner's syndrome and heterochromia are given hardly more than passing mention as symptoms in syringomyelia. Bremer in his studies found them in only a low percentage of cases of status dysraphicus. In this review we have stressed their occurrence since they are of great interest to the ophthalmologist. Passow's work gives the impression that these symptoms occur with greater frequency than is really the case. In searching for cases of status dysraphicus Passow used these symptoms as a guide and accordingly they occurred in a high percentage of his cases. It does not follow that they occur in all or most cases of status dysraphicus.

Passow felt that these cases offered clinical proof that the Horner's syndrome and the heterochromia could be explained by the same etiology as the other symptoms of status dysraphicus. He attempted also to supply experimental proof. Up to that time the question of whether heterochromia iridis might be the result of sympathetic paralysis had not been definitely settled. Many authors were unable to produce a depigmentation of the iris by sympathectomizing animals. Other investigators on the other hand had shown that interruption of the cervical sympathetic resulted in heterochromia. Passow, in his thorough experiments, showed that heterochromia followed a paralysis of the cervical sympathetic only when the paralysis occurred before development of the anterior layer of the iris and its pigment. He excised a portion of the right cervical sympathetic in young animals. Two or three months after the sympathectomy a lack of color was perceptible in the homo-lateral iris in those animals which were between six and eight days old at the time of the operation. In older animals, however, no heterochromia developed. Microscopical study of those irides which showed heterochromia revealed a decrease in (1) intensity of the anterior pigmented border layer, (2) number of chromatophores in the stroma, (3) intensity of the pigment layer. These changes were without evidence of inflammatory process. Passow concluded then that as Horner's syndrome is dependent on a disturbance of the motor fibers of the cervical sympathetic, so heterochromia is dependent on a disturbance of the trophic-vasomotor fibers.

Of course cases of acquired heterochromia and Horner's syndrome cannot be included in this group. While Passow has shown that Horner's syndrome and heterochromia frequently occur in status dysraphicus and are a result of sympathetic paralysis due to the dysraphy, there are nevertheless cases of Horner's syndrome and heterochromia which have no relation to status dysraphicus. Paling of the iris may follow trauma, or severe inflammation, or it may be a result of the ordinary workings of senility. Likewise Horner's syndrome is not found exclusively in status dysraphicus or syringomyelia, but may occur in association with various other diseases of the cervical cord and medulla, and in various lesions of the neck. A

quite satisfactory summary of these factors is given in a recent article by DeJong³⁰

The facts so far mentioned reveal that status dysraphicus is a distinct clinical entity. It is of interest to the ophthalmologist because of the frequent occurrence of Horner's syndrome and heterochromia iridis.

The similarity of the signs and symptoms of arachnodactyly and status dysraphicus becomes apparent as soon as one becomes familiar with the two conditions. Passow²⁷ pointed out this similarity in 1935. In arachnodactyly there is an over-length of the extremities, particularly of the hands and feet. The fingers and toes are unusually long, thin and tapering. In status dysraphicus the arms are too long and the span of the extended arms is greater than the body length. The hands are usually hypertrophic but in some cases may be very gracile. Web formation of the digits, funnel thorax, anomalies of the spine, winged scapulae, highly arched palate and anomalies of the external ears are common to both syndromes.

The eye findings, however, seem to be entirely different in the two conditions. In arachnodactyly we find congenital luxation or subluxation of the crystalline lens and poor reaction of the iris to mydriatics. In status dysraphicus there are heterochromia of the iris, Horner's syndrome and occasionally cataract formation. While the analogy of most of the symptoms suggests the relation of the two complexes, the ocular findings seem to show the contrary. It is possible, however, according to Passow to bring the eye findings of the two conditions together on the same basis. As was shown in the first half of this paper it is possible to explain all the findings in arachnodactyly, including the ocular, on the basis of a mesodermal maldevelopment. In status dysraphicus, the eye findings are explained by Passow as being the result of a dysraphy of the spinal cord, producing a paralysis of both motor and trophic-vasomotor fibers of the cervical sympathetic. And he believes all the symptoms of the disease are to be explained on a similar basis. As already mentioned, Weve² always found the lens in arachnodactyly very small, and the dilator pupillae muscle undeveloped. Passow explains these defects, as well as the ocular defects of status dysraphicus on the same basis. In embryonic life the lens is surrounded by a vascular membrane, the blood supply of which arises from the long posterior ciliary arteries. A dysraphy then, says Passow, could cause Horner's syndrome through paralysis of the motor fibers of the cervical sympathetic, heterochromia through paralysis of the trophic-vasomotor fibers of the sympathetic, and microphakia and ectopia lentis through trophic vasomotor disturbance of the tunica vascularis lentis in embryonic life. Actually an atrophy of the pigment layer of the iris and persistent pupillary membrane are quite frequent findings in arachnodactyly, as already mentioned by Weve² and Igersheimer²¹. Passow showed that after experimentally produced sympathetic paralysis in young animals there occurred not only Horner's syndrome but also a dystrophy of the entire iris, the ciliary body and the zonules.

It follows that one should be able to demonstrate cases of arachnodactyly showing evidence of status dysraphicus and vice versa. In reviewing the literature we found a few such cases mentioned, but, since status dysraphicus has been known for only a relatively short time, most observers simply did not look for signs of this anomaly in their cases of arachnodactyly. Brock³¹ in his case of arachnodactyly observed acrocyanosis, funnel thorax and spina bifida. Carrau,⁷ Weber,³³ and Boerger¹³ reported cases of arachnodactyly showing funnel thorax and kyphoscoliosis. Muscular weakness was often reported and this in some cases might be construed as a symptom of status dysraphicus, especially if the muscles involved were of the spinal group. We were unable to find any case of arachnodactyly with heterochromia iridis. One case was reported, however (Boerger), which may have had a Horner's syndrome. In this case he reported that the right lid fissure was somewhat larger than the left and the right bulb more prominent. We can only hazard an opinion that what this case actually showed was a small palpebral fissure and enophthalmos of the left eye (Horner's syndrome).

Passow reports two cases of his own which strengthen his idea of the similarity of the two conditions. The first, a 14-year-old girl, had spider fingers, luxation of the lens and eccentric pupils as well as heterochromia iridis and a difference in the size of the mammae, the smaller mamma being on the side of the paler iris. The hands were moist, cold and livid; there was deformity of the spine, webbing of the fingers, highly arched palate and increased reflexes. The second case, a 20-year-old boy, had spider fingers, luxation of the lenses and a heart lesion as well as overlength of the arms and heterochromia iridis. As to other symptoms he had funnel thorax, winged scapulae, and webbed fingers.

SUMMARY

Arachnodactyly is a little known developmental disease due probably to a maldevelopment of the mesodermal derivatives. Status dysraphicus is a distinct clinical entity to be explained on the basis of a mild form of syringomyelia. There are so many characteristics typical to both arachnodactyly and status dysraphicus that there is a reasonable excuse for believing the two diseases to be identical or at least closely related from an etiological standpoint. Passow's idea of the similarity of the two diseases has so many points in its favor that further reports are desirable either to confirm or disprove the theory.

CLINICAL MANIFESTATIONS AND STUDIES IN PARENCHYMATOUS HEPATITIS

By HUGO A. FREUND, B A , M D , F A C P , *Detroit, Michigan*

It is a paradoxical fact that one of the most accessible and important organs of the body, the liver, is the one about which the least is known. The multiplicity of its functions is appreciated but little understood. Therefore, for practical as well as theoretic purposes, any data concerning liver function, metabolism and pathology are deserving of record.

The baffling part of the liver problem lies in our inability to reproduce in animals conditions frequently found in man. Liver necrosis, hepatitis, cirrhosis, atrophy and regeneration have all been reproduced experimentally with varying degrees of success. These experimental lesions and their effects have been carefully studied. Yet none have been observed that satisfied every criterion. When morphologic alterations are produced, the physiologic changes may not strictly parallel those observed in man, in corresponding diseases, and vice versa.

Results approximating those seen in man have permitted simultaneous studies upon the pathologic histology and the physiologic chemistry. These studies have been carried on in animals suffering from acute or from prolonged liver damage induced by various types of hepatotoxins. In making comparisons, care must be taken in drawing conclusions, because powerful liver poisons produce disproportionate changes in different species. Furthermore, it has been shown that the previous diet of the experimental animal may, to a large degree, influence the results.

Among the many known chemical agents used to produce parenchymal liver damage, the effects of the hydrazine group have been extensively investigated. Bodansky, Underhill, Lewis and Izume have studied the action of the hydrazines upon liver metabolism in animals. They have shown that chronic intoxication with hydrazine and certain derivatives has interfered with the glycogenic function. Wells was able to show that hydrazine and its derivatives produced parenchymal injury to the liver of animals. The architectural structure of the liver was changed by early damage of the cells in the center of the lobule. The injury then extended to the periphery of the lobule, ultimately resulting in diffuse fatty changes. Wells in his early work stated that whereas other substances, such as the heavy metals, produced changes in other parenchymatous organs of the body, hydrazine limited its effects solely to the liver. Subsequent experiments have shown that this rather unique effect of hydrazine may be produced by a few other substances. In our series of animals studied thus far, acute intoxication pro-

* Presented at the Detroit meeting of the American College of Physicians, March 5, 1936

duced hepatic injury only. In man, however, chronic hydrazine poisoning resulted in changes in other tissues.

In addition to the histological changes in the liver parenchyma, hydrazine exercises another very important effect, namely that upon the glycogenic function of the body. Underhill and his co-workers as early as 1908 began studies of this problem. They noticed the marked hypoglycemia that results from the administration of hydrazine sulphate. This reduction in blood sugar was accompanied by an almost total disappearance of glycogen from the liver and from the muscles of the body. Underhill could offer no explanation for this effect. Bodansky, using the levulose tolerance test as a measure of hepatic injury, carried on extensive investigations of the variations in degree of liver damage produced by hydrazine and by certain hydrazine derivatives. His observations, which agreed with those of Wells, indicated that hydrazine sulphate produces fatty degeneration of the liver with almost complete disintegration of the hepatic cell without much apparent damage to other organs of the body. However, more complicated hydrazine derivatives and notably phenylhydrazine, when given to the experimental animal in quantities sufficient to cause "liver death," produced early changes in other organs of the body, notably in the kidneys, the spleen, and the bone marrow. He concluded that the hydrazine group constituted a powerful protoplasmic poison that acted chiefly upon the liver and seriously interfered with its glycogenic function.

Later, Izume and Lewis investigated the entire subject again. They concluded that hydrazine not only prevents the transformation of non-carbohydrate material into glucose and glycogen, but also prevents the synthesis of glycogen from glucose. This interference with glycogenesis interrupts the process of storage of glycogen in the liver. As a result the muscles are starved owing to the inability of the body to mobilize glycogen for their use. This condition is identical with that which Mann and his co-workers described in the completely hepatectomized animal. Intoxication with hydrazine and its derivatives results in a failure on the part of the body to form glycogen from glucose, from protein derivatives, and from fatty acids. That the synthesis of lactic acid is prevented also seems probable.

It was my good fortune to have the opportunity of studying the effects of a chemical compound from which hydrazine may be derived on two men exposed to the vapor of a nitrosamine. These two patients had repeatedly inhaled this chemical poison in sufficient amounts to produce headache, backache, abdominal cramps, nausea, anorexia, weakness, drowsiness and giddiness. They were poisoned in a rather unusual manner. Both were engaged as chemists in the production of dimethylnitrosamine to be used as an inhibitor for the prevention of corrosion. Their contact with this chemical substance was chiefly by inhalation. The first patient was assigned to the task of development and manufacture of dimethylnitrosamine. While engaged in this he became ill and could not continue his work. He

left the employ of the company for the purpose of seeking medical aid. It was approximately 16 months later that the second man was assigned to resume the production of the substance, at the point where the first chemist stopped. It was not until the second man developed symptoms and signs identical with those observed in the previous case, that the cause of these symptoms was suspected. The second man's intoxication followed repeated inhalations and the wiping up of a quantity of the substance that was accidentally spilled on the floor. He was the more severely affected of the two and died following an exploratory operation. Others who had worked in the same laboratory and had more or less contact with the suspected chemical substance were interviewed. All of them gave some history of dizziness, faintness, headache and weakness.

CASE REPORTS

Case 1 T. C., chemist, aged 29, single. The chief complaints are pain in the upper right quadrant, nausea, a sensation of weakness in the upper abdomen, and occasional abdominal cramps. He had cerebro-spinal meningitis at one year, and pneumonia and pleurisy at seven years. In 1925 he sustained an injury to one of his cervical vertebrae. In 1932 he suffered from what was diagnosed as "colitis" and anal fissure. He dates the beginning of his present illness to about July 1933, at which time he was engaged in the making of dimethylnitrosamine for commercial use. It was during the development of this synthetic compound that he began to feel ill. The patient states that on August 2, 1933, after he had been exposed daily to the fumes of this substance, he began to believe that the inhalation of it was making him ill, and he reported the fact to the company physician on that day. However, he continued to work irregularly up to August 15, when he felt so ill that he decided to quit. He complained of exhaustion, headache, cramps in his abdomen, deep soreness in his left side, nausea, some vomiting, occasional backache and utter fatigue. August 16 he noticed that his abdomen was distended and reported it to his physician who sent him into the hospital for further observation. On August 20 a paracentesis was performed and about two and a half quarts of fluid were withdrawn. Although the abdomen slowly filled again, no further tapping was resorted to. The patient states that he was told that he had "peritonitis," and that it probably was tuberculous in origin. He entered a sanatorium in Newburg, N. Y. Although he remained distended for some time no further paracentesis was performed. He remained in the tuberculosis sanatorium until January 1934, at which time he was discharged. Careful examination revealed no evidence of tuberculosis and the patient was returned to his home where he sought further medical advice because of the persistence of headaches, abdominal pain, and weakness. He remained in bed at his home until April 16, 1934, and then left to consult physicians in a large clinic in a hospital in New York City. He was thoroughly examined but nothing was found. A submucous resection was advised and was performed on May 25, 1934. He returned home to a small town in New York State, with instructions to rest. He rested all summer, enjoying a maximum of sunshine. Gradually the attacks of pain became less frequent. The patient states that he was jaundiced at the beginning of his illness. He also thinks that he had a short period of jaundice in the early part of January 1935. He is sure that he never had any fever. He has slowly regained his weight, which at one time he believes was about twenty pounds under his average. He admits that the entire illness has made him somewhat nervous and depressed. There is no history of clay colored stools. He does not remember passing dark urine.

His habits are good. He rarely takes alcohol. Smoked very little prior to 1933 and not at all since. He is a moderate eater. There is no history of tuberculosis, cirrhosis, or of any degenerative diseases in his family. His parents and brothers are all living and well.

FIG 1 Diffuse liver injury with multiple miliary hemorrhages

Physical examination reveals nothing of importance about his head, neck or chest. Blood pressure 132 systolic and 68 diastolic. His abdomen is slightly above the level of his ribs, and shows a moderate panniculus. There is tenderness throughout the whole abdomen on light palpation, especially in the right upper quadrant where there is definite muscle spasm. The liver is felt two fingers-breadth below the margin of the ribs, it is moderately firm and tender. The spleen is not felt. All reflexes and tests of sensation are normal. The non-protein nitrogen is 40 mg per cent. Blood sugar taken in the middle of the afternoon, after his noon day meal, was 66 mg per cent. Kahn test negative.

The patient promised to return for more study, but was not seen again until February 17, 1936, when he entered Harper Hospital. Physical examination at this time did not differ from the one made eleven months before. Studies of his blood and blood chemistry on this occasion were as follows:

Blood Count Hgb (Newcomer) 84 per cent Erythrocytes 3,680,000 Leukocytes 7,000 Color Index 11 Reticulocytes 1 per cent Thrombocytes 349,400 Differential Count Metamyelocytes 3 per cent, neutrophiles, stab 20 per cent, neutrophiles, segm 26 per cent, eosinophiles 0, basophiles 1 per cent, total of granulocytes 50 per cent, lymphocytes 48 per cent, monocytes 2 per cent

FIG 2 Acute intoxication with liver cell destruction Hyperchromatic and pyknotic nuclear changes

Urinalysis Fresh specimen color yellow, reaction acid, sp gr 1.015, albumin 0, sugar 0, urobilin 0, acetone 0, diacetic 0, bile 0 Phenolsulphonephthalein test Normal output and curve Non-protein nitrogen 30.9 mg per cent, icteric index 8, calcium 10 mg per cent, phosphorus 2 mg per cent Van den Bergh Direct, negative, indirect, slightly positive Takata-Ara test, negative Albumin-globulin ratio 9.43/4.95 Numerous blood sugar tolerance curves were done, all of which showed an increased tolerance Bromsulphalein test showed normal maximal dye elimination Kahn test negative Basal metabolic rate plus one Gastrointestinal roentgenograms revealed no abnormal findings Cholecystography revealed a normally functioning gall-bladder

During the patient's hospitalization, the pulse rate averaged 80 There was no elevation of temperature

Case 2 H B, aged 26, white, single, chemist, complains of pain in his abdomen, weakness, lack of appetite and headache He dates the beginning of his illness from December 1, 1934, at which time he began working on the job of pro-

FIG 3 Diffuse parenchymal injury showing nuclear changes in liver cells, mitoses, beginning leukocytic infiltration and thromboses in the small veins

ducing nitrosamine On December 12, 1934, he dropped a flask containing about one liter of this substance, spilling the contents He used an ordinary mop and rag to clean up the fluid He was very ill that night and the next day unable to return to work About December 18 he began to have pain in his upper abdomen, cramps and a feeling of distention He became constipated About December 20 his abdomen became more tender and the distention grew progressively worse There was a marked loss of appetite, slight nausea, but no vomiting He is uncertain as to the time that his skin became yellow, but believes that it began simultaneously with the enlargement of his abdomen His past history is unimportant There is no previous record of respiratory, cardiac, renal or gastrointestinal diseases He smokes 20

cigarettes per day, rarely uses alcohol. There is no history of cirrhosis, cardiac renal or vascular disease in his family. He entered the hospital on December 26, 1934.

Physical examination revealed an acutely ill patient, lying quietly in bed, pale and somewhat emaciated. The sclerae were slightly icteric, examination of the head was otherwise negative. Examination of the lungs revealed signs of free fluid in each pleural cavity. The heart was not enlarged, the heart sounds were clear and of good quality. Blood pressure 120 systolic and 76 diastolic. Nothing noteworthy was found about the peripheral vessels. The abdomen was distended and showed bulging on both sides. There was no visible venous engorgement. Both shifting dullness and a fluid wave were present. The abdomen was not rigid. The margin of the liver could be felt on palpation about three fingers below the right costal edge. It was tender. No other organs or masses were palpable. The genitalia were normal, no masses felt in the testes. Prostate and seminal vesicles normal.

On December 28 abdominal paracentesis was performed and 3,500 c.c. of fluid removed. Paracentesis was performed three times afterwards, at about one day intervals, 6,000 c.c. was the largest amount removed. Two c.c. of salyrgan were given intravenously daily for five days beginning January 10. At no time did the temperature rise above 99.2°. The pulse varied between 80 and 100, and the respirations between 20 and 26. I saw the patient in consultation on January 20. My examination confirmed the previous findings in all respects. On the following day paracentesis was again performed and 5,000 c.c. of fluid obtained.

Laboratory Findings Urinalysis (Jan 4, 1935) Fresh specimen, amber, clear, acid, sp. gr. 1.022, albumin trace, sugar negative, acetone negative, occasional hyaline cast, occasional pus cell, no red blood cells. Blood count (Jan 24) Hgb 80 per cent, erythrocytes 4,600,000, leukocytes 9,900, polynuclears 72 per cent, small lymphocytes 28 per cent, some variation in the shape and size of the red blood cells. Blood chemistry (December 28, 1934) Icteric index 16, van den Bergh reaction, faintly positive, direct and indirect. Kahn test negative. Roentgenogram of chest (Dec 27, 1934) Slight elevation of the right diaphragm. There is apparently a pneumonitis in the right base. Fluoroscopic examination shows movement of the right diaphragm. The remainder of both lung fields is clear. There is no evidence of pulmonary tuberculosis. Examination of ascitic fluid Sp. gr. 1.010, Wright's stain of centrifugated fluid showed a few red blood cells, and 61 per cent polynuclears and 39 per cent lymphocytes. Kahn test negative. Non-protein nitrogen 22.2 mg. per cent. Albumin 0.35 grams, globulin 0.38 grams, fibrinogen negative. Total protein 0.73 grams. Calcium 9.78 mg., phosphorus 3.55 mg., cholesterol, faint trace present. An exploratory laparotomy was performed. Summary of data recorded by surgeon: "Large amount of yellowish ascitic fluid. Liver extremely engorged, about a hand's breadth below margin of rib, smooth and purplish in color. Spleen markedly engorged and lobulated, purplish in color. Gall-bladder and duct somewhat thickened, no stones, emptied readily. Omentum retracted with many adhesions to the abdominal viscera. Appendix buried in a mass of adhesions. The pancreas appeared normal. The peritoneum and the mesentery were smooth and not injected. No tubercles were seen. The patient stood the operation poorly." He died on January 28.

Autopsy I am indebted to Dr. Lewis for the following notes. (Only data bearing on the condition are recorded.) Postmortem suffocation is extreme. Rigor mortis is marked throughout entire body. Conjunctivae, sclerae and the skin are slightly jaundiced. Superficial lymph glands are palpable. Right pleural cavity contains about 400 c.c. of serous fluid. Left pleural cavity contains about 100 c.c. of blood stained serous fluid. The pleural surfaces are everywhere smooth and glistening. The pericardium contains a slight excess of pericardial fluid. There are a

number of small subpericardial hemorrhages. The heart weighs 230 grams. The myocardium is light brown in color, very soft and flabby. There is dark blood in all the chambers, no agonal clots. Lungs. The right lung weighs 290 grams. The left lung weighs 320 grams. The left lower lobe is dark red, firm in consistency. There are small hemorrhages in the bronchi and trachea. The spleen weighs 320 grams. It is extremely soft. The pulp is uniform, mushy in consistence and rather darker than normal. There are some adhesions and some fibrinous exudate over the upper portion of the spleen. The gall-bladder contains about 20 c.c. of dark greenish-brown viscous bile. The biliary channels are patent. The liver weighs 1,380 grams. It is dark, greenish, mottled brown, rather firm in consistence. On section it presents a definite, greenish-brown, mottled appearance. The stomach is somewhat dilated. The mucous surface is thickened and the rugae are deep. In the prepyloric region there are numerous superficial hemorrhages and one small superficial ulceration, measuring 2 cm. at its greatest diameter. The duodenum, the jejunum, and the small bowel are not remarkable. The mesenteric lymph glands are markedly enlarged, and very pale and pinkish in color. The lower portion of the ileum is thickened. Its serous surface is covered by a firm, fibrinous exudate. There are occasional superficial hemorrhages scattered throughout the entire mucous surface of the small bowel. The appendix is long, retrocecal and covered by old adhesions. The adrenals are not remarkable. Kidneys. Combined weight of the kidneys is 300 grams. They are dark brown in color, the capsule is thickened and is fairly adherent to the underlying cortex. On section the renal markings are not well defined. Bladder and prostate reveal nothing abnormal. Summary of microscopic findings (P. S. Morse). Liver. Acute diffuse degeneration of the whole parenchyma with focal and diffuse areas of necrosis. The necrotic areas are infiltrated with round cells and phagocytes. Multiple periportaliliary hemorrhages. Areas of intense regenerative proliferation of liver cells with marked irregularity in size and staining reaction of protoplasm and nuclei. Kidney. Acute terminal passive congestion. Glomeruli and tubules normal. Some bile retention in tubules. Small intestines. Marked proliferative productive peritonitis. Thickening, edema and round cell infiltration of peritoneal coat. Heart muscle. Virtually normal, slight edema, no hypertrophy or muscle cell destruction, no fatty infiltration. Suprarenals. Normal cortex and medulla, no necrosis, no adenomatous zone, no small cell infiltration. Spleen. Postmortem autolysis, no cellular changes. Lymph nodes. Diffuse fibrosis, increase in size of coarse trabeculae, edema of gland as a whole, scarcity of germ centers. Bone marrow. Red marrow shows usual myeloid picture.

ANIMAL EXPERIMENTS

The nitrosamines have not been extensively used in industry. Manufacturers of the chemical had no occasion to suspect that its use, much less its inhalation, was fraught with danger. It is a clear yellow liquid soluble in alcohol, of surface tension one-sixth that of water. It has a slightly pungent, though not unpleasant odor. It is not particularly irritating to the mucous membranes. It has no corrosive action when applied to the skin.

In this instance it was intended for commercial use as an inhibitor of corrosion and a stabilizer. In the process of manufacture the following chemical steps took place:

As I was unfamiliar with the toxicity of dimethylnitrosamine and the literature contains no data bearing on the subject, it was decided to study the effects first upon mice, and later upon larger animals. A white mouse was placed in a one-liter jar, to the lid of which was fastened a gauze screen, saturated with 10 c.c. of dimethylnitrosamine. The jar was not sealed, a small amount of air being allowed to enter at the top. The immediate effect of the substance was irritation of the eyes, nose and skin, although the reaction did not seem to be a violent one. The respirations were not apparently affected. In a short time the mouse appeared sick and remained quiet. In 18 hours, mice subjected to one-half hour exposure to the fumes died in convulsions. Autopsy of such mice revealed nothing unusual on gross examination. There was perhaps slight injection of the peritoneum, some reddening of the bronchial mucosa. On microscopic examination the liver was the only tissue affected. There was diffuse regenerative hypertrophy and proliferation of liver cells. There was marked variation in shape and size and staining qualities of the nuclei of the liver cells. Marked irregularity of chromatin distribution was observed with pyknosis and autolysis.

A dog, weighing 12 kilos, was placed in a box and a small amount of air was permitted to enter. Gauze saturated with 30 c.c. of dimethylnitro-

samine was fastened to the lid of the box. The animal was kept in this chamber for 30 minutes. Except for occasional sneezing the animal did not seem to be irritated by the fumes of the substance. He was happy when removed from the box and showed no ill effects from the fumes. Eighteen hours later the dog had a mild convulsion. His blood sugar at that time was too low to read. Intravenous glucose was administered. Although the animal recovered slightly, it was impossible despite continued intravenous administration of glucose to influence the constant twitching. The blood sugar level could not be brought up to normal. The dog died in hypoglycemic shock. At autopsy gross examination revealed nothing abnormal in any of the tissues of the chest or abdominal cavity. Blood removed from the heart revealed no methemoglobin. Microscopic examination. The liver showed acute diffuse degenerative changes, evidenced by necrosis, especially in the region of the central vein with marked shrinking and acute atrophy of liver cells at the periphery of the lobule. This process had led to an enormous apparent widening of the bile capillaries. In the necrotic areas infiltration of phagocytes and phagocytosis had barely begun. Many liver cells had lost their staining quality in atrophic areas. Only the nuclei took the stain. Lungs. Acute diffuse pulmonary edema with acute terminal passive congestion. Relative atelectasis. The larger bronchi were filled with mucus and desquamated epithelium. Heart. Normal throughout.

A second dog weighing 10.5 kilos, was then subjected to inhalations of 10 c.c. of dimethylnitrosamine for a period of five minutes daily in the same chamber. The animal did not seem irritated by the exposure. On the fourth day the dog appeared less active than he had been previously. He played about, however, fairly well. On the fifth and last day that the dog was subjected to the inhalations he seemed less active. On the sixth day the sclerae and mucous membranes were distinctly jaundiced. The urine contained a moderate amount of bile. The dog drank glucose and water freely, but refused to eat. On the seventh day the animal twitched occasionally. There was no spasticity. Vomitus of clear fluid on two occasions. The gait was somewhat unsteady but there was no paralysis.

Autopsy. There were no abnormal findings in the gross examination. Microscopic findings. The liver showed uniformly distributed diffuse hemorrhages around the central veins, which extended peripherally and did not involve the portal area. No changes were noted in the pancreas, spleen, suprarenals, kidneys and heart muscle.

Experimental cirrhosis resulting from hepatic injury has been produced in many ways. Moon has completely reviewed this subject. Of all the hydrazines only phenylhydrazine is used in the practice of medicine. Its pharmacologic action is well understood and differs greatly from that of many hydrazine salts. Hurst and Hurst were able to produce cirrhosis with ascites by the simultaneous administration of hydrazine sulphate and manganese dioxide. In their animals a diffuse parenchymal destruction took

place involving the entire liver lobule which differed histologically from the effects of dimethylnitrosamine.

In all likelihood this difference is due to the fact that dimethylnitrosamine is carried by the arterial blood to the liver cell where it exerts at least a twofold action, firstly it causes liver cell destruction and secondly it is glycogenolytic. In this respect it differs from other hepatotoxins that have been studied, and by the same token it affords another method of approach to the study of liver problems.

SUMMARY

The chief points in our knowledge of the toxic parenchymatous hepatitis due to dimethylnitrosamine may be summarized as follows:

1. Dimethylnitrosamine is a volatile toxic substance which upon inhalation exerts a destructive action on the liver. Its use should be considered as an industrial hazard. Its immediate and remote toxicological effects have been described. It probably is reduced in the liver to a hydrazine and acts in that form.

2. The primary seat of action is about the center of the liver lobule where it produces a degenerative necrosis of the liver cell. Continued and more intensive poisoning results in the destruction of all liver cells. Ultimately partial bile duct obstruction takes place.

3. Dimethylnitrosamine destroys the glycogenic function of the liver. Hypoglycemic shock, in all respects resembling that seen in the hepatectomized dog, may be produced with dimethylnitrosamine. When recovery takes place, glycogenesis is impaired. Muscle glycogen reserve is diminished.

4. Two human cases are reported of toxic parenchymatous hepatitis with ascites, due to poisoning with dimethylnitrosamine. Toxic portal cirrhosis with ascites may be experimentally produced with dimethylnitrosamine.

PAIN AND PAIN EQUIVALENTS IN HEART DISEASE

By CLOUGH TURRILL BURNETT, M D , F A C P , *Denver, Colorado*

APPROXIMATELY 90 per cent of all non-traumatic sudden deaths are cardiovascular in origin, and 65 per cent are due to coronary artery disorders. A study of these cases of sudden death demonstrates a strikingly large number who gave a history of precordial or near-by pain preceding or during the fatal illness. The majority of these show pathological evidence of antecedent changes in the coronary vessels—namely sclerosis, but these changes were not the cause of death. Some added mechanism caused a sudden cardiac standstill.

This tragic event—sudden cardiac death—is well known even to the laity, but the symptoms leading up to it are not so well known, nor is it sufficiently recognized that practically all of the earlier symptoms may be encountered in disorders not at all associated with the cardiovascular system. Of these early evidences of coronary disorder, pain is both numerically and psychically the most important manifestation. Because of this frequency of pain and its effect upon the patient's morale, a consideration of the various types of cardiac pain, their origin and distribution and associated symptoms and signs will be presented, and an attempt made to differentiate pains which are a manifestation of cardiac disorder from those arising from other tissues, and tending to cause diagnostic confusion.

At a period when anatomical changes occupied the center of the medical stage and before disturbed physiology was seriously considered as a cause of disease processes, Heberden in 1768, under the title "Some Account of a Disorder of the Breast," gave the first clear description of the condition since known as angina pectoris. He stressed the importance of nervous and mental influences and stated that this condition belongs to the class of the spasmodic, rather than that of the inflammatory complaints. Throughout the history of this disease it seems apparent that medical men are peculiarly susceptible to it. John Hunter recognized the rôle of emotional strain and wrote that his life was in the hands of any rascal who chose to annoy him. He died in a fit of temper. But that emotional strain was not the sole factor was suggested by Jenner in 1799 when he described the frequent association of angina with disease of the coronary arteries. Three years before he had seen Hunter in his second attack and suggested in a letter to Heberden this probable association.

It was not until about 50 years after Heberden's first article that Reeder (1821) suggested that many other conditions might produce a type of precordial pain sufficiently similar to justify the use of the term "pseudo-angina." From this period until the latter part of the last century there was

* Received for publication October 8, 1936

little added until the writings of Mackenzie, Allbutt, Wenckebach, and Osler, who in 1897 stated that angina pectoris is "not a disease but a syndrome or symptom complex" Sir Clifford Allbutt, in a letter to Dr Robert L. Levy¹ gave his last definition of angina pectoris "Angina pectoris is a pain, sometimes slight, sometimes agonizing, arising usually under the sternum and referred in certain definite directions, due to stretching of the outer coat of a morbid aorta, or in a few cases of that of the heart itself This is my first hasty suggestion for your 'definition'"

In late years the term pseudo-angina has largely been discarded, although as recently as five years ago Harlow Brooks² used it to designate a condition "where anatomic defects do not exist in the heart or aorta, whereas in true angina pectoris I hold that lesions exist to a recognizable degree in practically all instances" He believed that most patients with pseudo-angina were neurotics, but appears not to have taken into account the existence of a significant number of instances of true angina pectoris in which neither physical nor electrocardiographic examination reveals unequivocal evidence of heart disease Current writers employ the terms angina pectoris and anginal syndrome synonymously, although the present tendency is to modify the latter with a qualifying phrase as to etiology

Throughout this later period there have been three main theories of pain production in the heart Allbutt believed that the pain arises in aortic lesions mainly Opposed to this was the teaching of Mackenzie that the pain was due to exhaustion of the myocardium induced by coronary artery disease Closely related to this was the theory of Allan Burns who in 1809 attributed the pain to anemia of the heart muscle Sigler³ recently shows that the carotid sinus reflex is increased in the vagotonic individual and suggests that resultant coronary vasoconstriction and myocardial ischemia may be the cause of angina At the present time, the majority of workers consider ischemia of the heart muscle as the most acceptable cause of angina pectoris But that this is not the sole cause was shown by Katz⁴ recently While bodily exercise and generalized anoxemia may precipitate attacks in patients subject to anginal seizures—usually with rather characteristic alterations in the electrocardiogram, which are similar to those occurring in spontaneous attacks—Katz⁴ has demonstrated that similar ischemic changes may be experimentally produced in normal persons without causing precordial pain, which observation leads this author to conclude that some other factor than ischemia plays an important rôle In animal experiments Katz shows that "Continuous pain can be produced in contracting skeletal muscle when the muscle is rendered ischemic", that in the dog "Pain response was not due to the occlusion of the coronary artery, but to stimulation of afferent pain fibers located in the nerve plexus surrounding the vessels" He concludes "The stimulus for pain appears to consist of some metabolic product produced quantitatively in proportion to the work done by the heart The amount of the product produced is increased when the heart works ineffi-

ciently, especially when the diastolic blood pressure is elevated, because the heart has to exert more effort in raising the pressure of its contents above the diastolic aortic pressure "

Evidence ⁵ derived from experimental arrest of the circulation of the human limb, carried out with and without associated effort, seems to justify the belief that whenever, in the presence of sclerosis or other coronary artery obstruction, the work of the heart is so increased that the demands upon the coronary circulation exceed the vessel capacity—anginal pain ensues. These experiments showed likewise that fatigued muscles failed to exhibit pain under similar conditions, suggesting an explanation for the clinical observation that the failing heart muscle is rarely associated with anginal attacks.

Thomas McCrae ⁶ challenged the idea that angina pectoris is always due to coronary disease and believed that we should regard this disease as one having a multiple etiology, including myocardial disease, viscerosensory reflexes, and possibly purely neuro-psychic mechanisms. It is certain, at least, that extra-cardiac factors precipitate attacks. Early gastric lavage prevented attacks in one patient, in another prostatic treatment "cured" the angina. I have in mind also a man whose anginal attacks were relieved for a period of many months following a cholecystectomy, yet later he again suffered from angina and died in his second attack of coronary thrombosis.

In a very recent report ⁷ experimental and clinical evidence is presented in support of the statement that "Angina pectoris is due to acute, spasmodic, incoordinated contractions of the esophagus and stomach." Dr. Jackson's presentation of this subject at the Kansas City meeting of the American Medical Association was quite convincing, but corroboration must be forthcoming before such a novel theory can attract more than passing interest.

Warthin ⁸ taught that syphilis plays an important rôle in the causation of atherosclerosis, hence that coronary thrombosis and angina pectoris occur more frequently in syphilitics. To all of Warthin's students it was well known that he found evidence of syphilis where his contemporaries were unable to satisfy themselves as to its occurrence. Scott ⁹ also found one-half the cases of coronary artery disease dependent upon syphilis. Others do not find that syphilis predisposes to coronary sclerosis. Certainly present day teaching ¹⁰ does not stress syphilis as a cause of angina pectoris. The race in this country most extensively invaded by syphilis, the negro, shows a notable freedom from the anginal syndrome. Roberts ¹¹ of Atlanta offers as an explanation of this fact that the negro "never worries very long about any one thing at any one time," and suggests that "the white man's burden is his nervous system." An English physician, Donnison, ¹² who had a considerable experience in the Orient, stated that he had never seen angina pectoris in natives in Central Asia or China. An inquiry directed to a physician of 40 years' experience in India corroborates this observation. Wenckebach ¹³ noted as early as 1904 the marked difference in the incidence

of angina pectoris among a rural population as compared to that of the cities, but when he went to Vienna he observed a marked increase in these cases in his practice, and also that there was a further significant increase in the years of and after the War, which increase he attributed to worry and strain.

It is probable that the presence or absence of the anginal syndrome is to a considerable extent dependent upon the degree to which the nervous system of the individual is sensitive to various influences, physical and psychic, for it has been amply proved that extensive limitation of the coronary circulation may exist without pain or other evidence of the anginal syndrome. It may be assumed that such individuals have a high threshold of sensitivity to those influences which act as a "trigger mechanism" and set off the painful attack in susceptible individuals. There is some evidence that this "trigger mechanism" is associated with an endocrine imbalance, since adrenalin is known to precipitate attacks in individuals subject to angina and not in controls.

It appears that there is no constant toxic or degenerative etiology, and that angina pectoris must be looked upon as the result of a combination of reactions in the nervous and circulatory systems induced in certain individuals by the stress and strain of life. In general, angina pectoris is noted in the aggressive, head of the procession, stocky individual, rather than in the neuro-circulatory under-nourished type.

Until fairly recently angina pectoris was considered, if not definitely as a disease of the intelligentsia, certainly as a disease of the upper classes, but even this idea is losing ground. Many¹⁰ doubt the importance of occupation. It has been pointed out¹⁴ that while "occupation does not appear to play a significant part in determining those whose coronary arteries are affected by sclerosis—with respect to the occurrence of pain, however, occupation seems to be of real importance," and that pain occurs in a significantly higher percentage of housewives and manual laborers than in clerical, skilled workers and professional men. These conclusions are drawn from pathological records of the Presbyterian Hospital of New York City where the women occupying the ward beds are usually of the hard working class. Probably, records drawn from groups more fortunately situated may not agree on this point. It is notable that the former predominance of males is diminishing, probably due to entrance of women into the stress of industrial, business and professional life.

Several writers have suggested that the "heart mindedness" of the laity during the past two decades may play an important part in the apparent increase in the various manifestations of coronary artery disease. This may be a factor in the increased frequency of precordial pain, but it seems more probable that the mode of life of the past two generations has led to a progressive increase in vascular degeneration, especially of the coronary vessels—to quote Osler "in the make-up of the machine, bad material was used for the tubing," and with the increased strain of the past two decades

the "tubing" is inadequate to the strain. Most of us are aware of families showing this type of defective "tubing." But in the members of such families in whom we encounter pain as a presenting symptom, we will almost invariably find excess strain of some type as a precipitating cause of the painful attacks.

The mechanism of the pain production in these cases has been the subject of numerous essays, the majority favor the view that in some manner a transient ischemia of the heart muscle occurs. In occlusion of the artery, either slowly produced or by sudden thrombosis, there is no question as to the production of anoxemia, but whether in the paroxysmal transient attacks of precordial pain coronary spasm occurs is an unsettled question, although it seems the most reasonable explanation. That disturbed metabolism may be a factor in the induction of spasm is established by the work of Blumgart¹⁵ and his associates. These authors have reported a significant number of instances of complete relief of pain in angina pectoris following total thyroidectomy. Beach¹⁶ and others have noted similar relief following subtotal thyroidectomy. It is conceivable that a vagus pressure mechanism is present in some of these thyroid cases, but it is usually conceded that the lowering of metabolic rate, and hence of the circulatory demands of the body, is the basis of the improvement.

The question is often raised why heart pain is not felt in the heart. The answer entails an intimate knowledge of the visceral nerve supply. Ordinarily painful sensations do not arise in the heart, therefore, the brain is not accustomed to recognizing heart pain, hence when an adequate stimulus occurs the pain is frequently registered as from some other body area. The factor of spread of impulse has to be taken into consideration, since in many instances of excessive heart pain there is an overflow to adjacent areas. Less readily understood is the mechanism involved in those anginal cases in which the pain is first appreciated at some point well removed from the heart, whence it is transmitted to or towards the heart—a reverse radiation process.

AGE AT WHICH THE ANGINAL SYNDROME APPEARS

Most cases of angina occur after 50, but there is ample evidence that childhood and early adult life are not exempt. Heberden had one case at two years. There exist reports of a seven weeks infant¹⁷ which died suddenly and at autopsy showed advanced degenerative coronary changes, and of a 13 year old girl whose left ventricle ruptured due to advanced coronary sclerosis. There is evidence¹⁸ that coronary narrowing may be a sequel of acute rheumatic carditis and manifest itself as early as the second decade, and that these patients not infrequently suffer from severe and typical anginal pain. There are numerous instances in the third and fourth decades.

An associated study of importance in this connection is that of the pathology of coronary sclerosis.

Leary¹⁹ has demonstrated this change as early as the third day of life, and finds it is "not rare in the first decade, more common in the second with fatal thrombosis in the third and later decades" He believes that "Atherosclerosis is a disease and not the inevitable consequence of age," and that it is due to a disturbance in the cholesterol metabolism

RELATIONSHIP BETWEEN ANGINA PECTORIS AND CORONARY THROMBOSIS

In patients with coronary artery disease angina is apt to follow strain, physical or emotional, whereas when coronary thrombosis occurs its onset is often while the patient is at rest Certain instances of angina occurring during sleep may be the result of strain during a night-mare Either type of seizure may occur with or following meals, a reflex effect that is not understood Leuten²⁰ reports two instances of coronary thrombosis which followed closely upon the taking of a cold drink In such cases there are two possibilities, a reflex coronary constriction with sequential thrombosis or a direct effect of cold upon the heart Several workers have demonstrated changes in the T-wave of the electrocardiogram following the ingestion of cold water, but in these instances there was a considerable amount of water taken which may have caused an axis shift capable of producing similar changes in the T-wave

Anginal seizures preceded the final occlusion in 22.4 per cent of 370 cases of coronary thrombosis, and in 45.1 per cent persisted or appeared after the occlusion²¹ These figures appear to disprove the earlier idea that anginal attacks are not observed following occlusion It is probable that the temporary muscle failure sequential to the infarct causes the disappearance of the former painful attacks, but with recovery these may be renewed

No attempt will be made to differentiate the type and reference of pain occurring in angina and in coronary thrombosis The diagnosis rests in part upon the antecedent history, the occurrence of preceding similar attacks, especially in angina, and the presence or absence of a strain factor, but in each the immediate pain may be identical in type, in point of origin and in distribution It is the sequence of events which tells one whether this attack is a recurrence of angina pectoris or a new situation to be dealt with—coronary thrombosis Various authors have differentiated cases by the occurrence of high or low substernal pain and the reference of this pain to one or both arms The writer is unable to make such a differentiation Likewise, there is too often an absence of the crushing, tearing, agonizing pain of the classical textbook description When this picture occurs diagnosis is made easier, but because in either angina pectoris or coronary thrombosis the pain may be mild or absent, or may originate at a point apparently not related to the heart, or may not be referred to either arm and even not transmitted beyond its point of origin—because of this variation in symptomatology, some consideration of those symptoms which may take the place of pain and their importance in diagnosis is in order

Usually the anginal patient during the short attack remains quiet, rarely even moaning, there are no theatrics, as so often noted in the cardio-neurotic who complains of pain. After the attack is over he tells of his pain. The observer is keenly aware that momentarily the patient is in agony. While the attack is ordinarily immobilizing, that is, the patient "stops in his tracks," there are some who continue walking at a slower pace with relief. I have under my care at the present a man of 69 years who has frequent attacks (I have seen him in one severe seizure), and whose greatest relief comes with slowly pacing around his room. Wenckebach²² compares this with "second wind," a physiological phenomenon of which we know remarkably little. Contrast both of the foregoing with the restless and panicky seizure associated with tobacco sensitiveness.

As a rule, the anginal attacks are of short duration—a few minutes, very rarely 15 to 30 minutes, a point of differentiation between angina pectoris and coronary thrombosis, for in the latter the pain continues until relieved by morphine, unless of the very mild or painless type. In both conditions the pain is uninterrupted, though there may be slight changes of intensity which are not dependent upon drugs. On the other hand, in the neuroses there is a notable variation in the intensity of the pain as described by the patient.

Dyspnea is not a common accompaniment of pain, though occasionally a paroxysmal dyspnea appears with the pain. In one reported case²³ the attacks could be averted by deep breathing.

In certain instances in which pain does not occur the patient may remain perfectly still during the attack and in every respect behave precisely like a patient experiencing the usual agonizing pain. Patients frequently experience in their seizures other symptoms in lieu of pain and such symptoms may be considered as equivalents of pain. According to Libman²⁴ these pain equivalents are more frequently noted in individuals who are hypersensitive to ordinary painful impressions. Not infrequently, in lieu of pain, dyspnea of an arresting type is experienced. This is sudden, paroxysmal, often nocturnal and accompanied by the classical sense of impending death, lasts during the attack and may disappear as suddenly as it appeared.

A similar clinical syndrome in which the dyspnea does not disappear may be due to a thrombotic closure of a coronary vessel.

I have seen several instances of coronary occlusion in which the predominating and initial feature was sudden dyspnea. Two seizures occurred by coincidence in a theater. In one a well known actor was forced by dyspnea to stop in the midst of his lines, in the second instance a woman of 50 years was seized with such sudden and urgent air hunger that she had to be carried from the theater. She had no pain at any time, but a terrifying dyspnea, yet she presented all of the usual signs of infarct, including a pericardial rub. Both of these cases showed unmistakable evidence of occlusion, neither had significant pain.

Profuse localized sweating may occur as an equivalent of pain. Such sweating should not be confused with that which commonly occurs with the shock of coronary thrombosis, nor with the less marked sweating of angina pectoris.

Palmer²⁵ reports a case of a physician of 61 years who, two weeks after an attack of precordial nocturnal pain, lasting one hour and requiring morphine, awoke to find the precordium, shoulder and left arm drenched with sweat, elsewhere no sweating. There was no pain, pressure or heaviness. He had had similar painful attacks two and six years previously. This case is reported as a case of angina pectoris.

Mackenzie notes local flushing and sweating with angina pectoris attacks. Vaquez notes fleeting vasomotor phenomena in angina pectoris. Osler²⁶ described one case in which profuse sweating preceded an attack of pain by one-half hour which, however, may have been an attack of coronary thrombosis with late pain. These changes represent reflexes from the heart or aorta to sweat glands, ciliary muscle or to end organs in the abdominal viscera.

A doctor of 67 years who, at the onset of his attacks had typical anginal seizures and later an occlusion, has during the past two years had attacks without pain initiated by marked salivation, nausea, and vomiting. If he stops at the onset of the attack, only the salivation occurs. After the attack he voids copiously. This has recurred frequently and over a long period and has not been associated with physical or electrocardiographic changes indicative of infarct. Save for the absence of pain and the symptoms described, the patient's sensations are those of his former anginal attacks.

Paroxysmal headache, vertigo, nausea and vomiting, and a sudden feeling of great weakness have all been described by reliable clinicians²⁷ as pain equivalents in angina. In some instances these appeared in the course of a classical angina as phenomena substituting the pain, in others they represented the presenting symptoms in a patient who was thought to be free from any cardiac complaints, yet died suddenly and showed at autopsy coronary or aortic disease without other cause for sudden death. It is probable that the vagus nerve plays a rôle in this confusing symptomatology. This nerve furnishes not only motor, but large sensory branches to both the gastrointestinal tract and the heart. In addition, there are numerous sympathetic pathways between these two systems. By either of these routes it is possible for pain or other symptoms to be registered as from a tissue in which it does not truly arise.

RELATIONSHIP BETWEEN THE SYMPTOMS OF CORONARY DISEASE AND CONGESTIVE HEART FAILURE

Angina and heart failure are antagonistic conditions. The failing heart is incapable of causing the true anginal seizure. With the control of failure

with digitalis, the muscle may recover sufficiently to cause a return of the painful attacks which existed prior to decompensation. In failure, local anoxemia exists, the muscle performs inefficiently. Certainly disturbed metabolism of the heart muscle is present, but nothing comparable to the seizure of angina pectoris occurs unless coronary thrombosis develops. The most satisfactory explanation for this so far advanced is the fatigue anoxemia theory previously mentioned.

When occlusion occurs in the course of heart failure, if not immediately fatal, the symptoms characteristic of thrombosis may not appear at all. To the existing failure there is only an increase in already existent symptoms, often without any acute pain.

THE ELECTROCARDIOGRAM IN CORONARY DISEASE

The changes in the standard lead electrocardiogram in coronary thrombosis are too well known to require more than passing comment. These changes in the R-S-T complex are initiated within a few hours of the onset, rarely returning to normal within six to twelve months, and there are permanent alterations in about 25 per cent of cases. As a rule, in addition to fusion of the R- and T-waves, there are distinct T-wave changes, generally some degree of inversion, but this is inconstant. Lead IV or some type of chest lead has offered some assistance both in diagnosis and prognosis, but with this technic normal variations introduce considerable confusion, perhaps more than in the case of the standard leads. Until cardiologists can agree as to a standard or standard chest leads, cardiographic diagnosis must rest upon the original standard leads. While the electrocardiogram is of great value in diagnosis in many instances, it must be admitted that exact correlation between the lesion and the electrocardiogram is impossible.

Because of the progressive changes which take place after an acute closure of one of the coronary vessels, the greatest amount of information will be derived from serial electrocardiograms, preferably taken daily. In this manner transitional changes will be shown, which would be missed in single records. This need for serial curves in cases of suspected acute occlusion is manifested by the fact that in rare instances tracings may remain normal or only slightly abnormal for several hours following occlusion, a point of importance in the differential diagnosis of coronary thrombosis and of acute surgical conditions in the abdomen. Hurxthal²⁸ warns against too great reliance upon the electrocardiogram in such instances. Furthermore, changes in the curves characteristic of infarct may be produced by myocardial ischemia brought on by a sudden myocardial insufficiency when the force is insufficient to drive the blood through narrowed or even normal coronary vessels, there is not acute closure of the vessel, but ischemia just as surely follows.

The serial changes described as characteristic of infarction take place in a fairly short space of time, ordinarily hours to days. Similar

changes developing more slowly are known to be associated with a myocardial fibrosis sequential to a chronic progressive coronary sclerosis, therefore, it is necessary to consider the time element in the interpretation of progressive changes in the R-S-T complex

There are a few records of electrocardiograms during a spontaneous attack of angina pectoris²⁹ and several during induced attacks, in all of these the T-wave becomes flat or inverted and the S-T interval depressed.⁴ In 75 per cent of 40 anginal patients similar changes followed effort, not necessarily associated with³⁰ pain. Experimentally induced anoxemia furnishes curves identical with the preceding, but these are transient, completely disappearing with adequate oxygenation.³¹ It is probable, therefore, that myocardial ischemia is the immediate cause of these changes observed during attacks of angina pectoris

In spite of all that has been stated regarding anoxemia as a cause of anginal pain and its association with coronary sclerosis, the fact remains that fully one-third of the patients with angina pectoris present entirely normal curves in the standard leads of the electrocardiogram. It seems probable that further observations with chest leads will show changes in this derivation, both in the patient with mild coronary sclerosis and in the one subject to anginal attacks. However, until this technic becomes standardized we must recognize that the electrocardiograph fails to detect about 33 per cent of the cases in this group

OTHER CONDITIONS IN WHICH PAROXYSMAL ATTACKS OF PRECORDIAL PAIN MAY OCCUR

In many normal individuals hypochondriac or precordial pain or ache may follow effort. Usually this is low in origin,—probably never higher than the arm or shoulder. It is often lancinating, knife-like and of sudden on- and off-set. Due to the popular knowledge of sudden death in painful heart disease, there may be an associated anxiety suggesting the *angor animi* of angina pectoris, but rarely the compressions noted in angina pectoris. Not infrequently there is precordial tenderness associated with pains in this region which are not due to heart disease

Esophageal or gastric distention may cause apical pain and may be relieved by belching or removing gas by the stomach tube

Rhythmic or arrhythmic paroxysmal tachycardia may give rise to precordial pains of varying intensity. These are not usually of the type and severity which would cause confusion with angina pectoris, moreover, the patient clearly recognizes the sudden disturbance in rhythm, and it is not as a rule until this has continued for some time that pain is significant. The associated drop in blood pressure may so reduce the coronary flow that anoxemia develops. Rarely does the picture of shock appear until the attack has continued over many hours. I have seen recurrent precordial pain and tenderness in a boy of 17 years whose paroxysmal auricular tachycardia

returned each time digitalis in large doses was withdrawn. White³² reports an exceptional case of bilateral anginoid pain severe enough to justify a consideration of alcohol injections, and four cases in which definite attacks of angina pectoris were brought on by paroxysmal auricular fibrillation or flutter.³³

Certain patients who are found to have sclerosed coronary arteries exhibit pain of less sharp though paroxysmal character, due to intermittent ischemia. Rest and vasodilators furnish relief. These pains may show some radiation, but in none of this group are the associated symptoms of angina pectoris present. This syndrome may represent an early manifestation of angina pectoris, yet many of these patients (perhaps one-third) will, with proper management, show nothing more for years.

Experimental studies³⁴ indicate that anoxemia plus work results in pain in the muscle involved, an observation which seems adequately to explain the effort pain observed by the patient with coronary sclerosis. Not all cases of coronary sclerosis complain of pain, about 20 per cent develop an ultimate myocardial failure without pain at any period, the balance (80 per cent) complain of pain or dyspnea at some time. The pain in this group is characteristically a sense of fullness or pressure, like a constricting belt rather than an acute pain. It is usually substernal or precordial, and in only about one in ten does it show any significant radiation, and then more often to the epigastrium, when, if accompanied by nausea and vomiting, the impression of an acute indigestion is strengthened. Dyspnea may be suffocating and not at all associated with exertion, in fact, the dyspnea of coronary sclerosis is most frequently nocturnal. There are instances of relief from mild exertion. This type of pain is to be differentiated from angina in that it is not dependent upon effort, worry or cold, is less paroxysmal, and there is no associated and characteristic posture, some degree of dyspnea rarely being absent.

An easily differentiated type of precordial pain is that associated with advanced myocardial disease. Here the pain is rarely of the severe arresting type, is precordial and without radiation. This pain, the associated dyspnea and peripheral signs of failure, often clear under digitalis therapy.

In advanced valvular disease, especially stenosis of the mitral and aortic valves, paroxysmal pain may occur. In the first instance it is thought that the coronary vessels are collapsed following sudden increase in intra-auricular pressure, in the second, sudden drops in an already reduced pulse pressure lead likewise to a decreased coronary flow.

Mention has been made of disturbed thyroid function. In both hyperthyroidism and in the hypothyroidism of myxedema rather typical anginal symptoms may occur. Approaching diabetic coma and the hypoglycemia of insulin shock may be accompanied by such a painful picture. Not infrequently in profound anemias painful attacks occur which strongly suggest angina pectoris. In this condition the myocardial demands exceed the available oxygen supply and a transient myocardial anoxemia ensues.

Rupture of the aortic valve or of an aneurysm of either the thoracic or abdominal aorta may present the clinical picture of coronary thrombosis. In one such instance³⁴ an electrocardiogram characteristic of infarct was obtained, which may have been due to a relative myocardial ischemia without infarction.

The upper abdomen presents surgical emergencies which often are only with great difficulty and loss of time differentiated from acute coronary occlusion. Because the electrocardiogram is at times a bit tardy in presenting its evidence, it behooves one to weigh all clinical evidence carefully before denying surgery. An exploratory operation in the presence of an infarcted heart is no greater error than an unoperated ruptured ulcer.

Not all of these abdominal conditions which may become confused with angina are potential surgical emergencies. The sigmoid colon may give rise to transient pains which appear to arise in the precordium and may even radiate to the shoulder and arm. The associated anxiety state induces palpitation and arrhythmia, thus completing a cardiac picture.

An occasional source of confusion is a pulmonary artery embolism. The immediate signs and symptoms may be identical with those of coronary occlusion. If the left lower lobe is infarcted there will be in a short time an accompanying pleuritis which may overlie the pericardial sac. Here the initial symptoms, the fever, leukocytosis and the apparent pericardial rub, all point to the heart as the primary seat of trouble. If this occurs in a patient with evidence of peripheral varicose veins or phlebitis or after operation, the likelihood of embolus is strengthened. Fortunately, the early management of such cases is so nearly identical that a diagnostic error is not very serious.

Spontaneous pneumothorax may for a time be confused with occlusion, the resulting enfeebled heart sounds, signs of shock, and thoracic pain being readily attributed to the heart. About 25 years ago, even before we were as "coronary conscious" as at the present period, I saw such a condition in a man in his late thirties in whom, there being no antecedent pulmonary history, the heart was under suspicion until roentgen-ray showed a small anterior pneumothorax not demonstrable by physical means.

Another pulmonary condition which, according to Hamman,³⁵ is likely to be confused with coronary thrombosis is spontaneous interstitial emphysema. The sudden tearing of mediastinal tissue may produce severe pain, although I have observed two instances which occurred in the course of induced pneumothorax, which were not accompanied by any appreciable pain, though sufficient to lead to a widespread emphysema of the cervical tissues. Hamman describes a peculiar "crunching sound" with each heart beat which might be mistaken for a pericardial rub.

Aside from the painful seizures of angina pectoris, the only heart condition which should be confused with coronary thrombosis is the occasional instance of pericarditis, often pneumococcal in origin, in which the pain

comes on as suddenly as in coronary thrombosis and is very severe and may radiate to the arms. This may shortly be followed by evidence of myocardial insufficiency. Here the complete clinical picture of coronary thrombosis, pain, dyspnea, circulatory failure, collapse and eventual congestive heart failure, combined with a pericardial rub, may tax diagnostic powers. Added to this picture we have electrocardiographic changes due to pericarditis which may suggest occlusion. A differential point is that in pericarditis the rub is louder, over a greater area and more constant, while in cardiac infarct the rub when present is faint, usually transient and limited in the area over which it is heard. A demonstrable pericardial effusion is rare in cardiac infarct.

The pain of sub-deltoid bursitis may simulate that of coronary disease, and in cardiac infarct persistent shoulder pain may direct attention away from the heart. Mild or severe, burning, aching or wrenching pain in the shoulder region was encountered in 10 per cent of 14 survivals from coronary thrombosis.³⁶

Disturbances of the spine and nerve roots presenting the radicular syndrome, when involving certain cervical and dorsal segments, may present a pain pattern very like that of true angina. These are commonly associated with postural defects and fatigue, and may be temporarily increased by anything which increases intra-spinal pressure, namely, coughing, straining, et cetera. Such phenomena as nausea, vomiting, and vasomotor changes, which are commonly associated with the pain of thoracic visceral disease, are not present in even the most extreme instances of root pain, and this pain is not relieved by nitrites.³⁷ A policy of "watchful waiting" in doubtful cases may relieve one of the embarrassment of changing the diagnosis of angina to one of herpes zoster, sciatica, lumbago or some other complication of spinal cord disease.

Diaphragmatic hernia has been confused with angina pectoris. In a recent report³⁸ a case of "diaphragmatic flutter" was described as simulating angina pectoris. The same patient subsequently came under my observation and will be the subject of an early report. This man entered the hospital with an admission diagnosis of angina pectoris, but was seen by me during an attack. That there was pain was evident, but here the patient was in constant motion and agitation and pounded his left precordium so violently it was thought that subsequent tenderness resulted therefrom.

This patient well illustrates the subject of false angina, the pseudo-angina of some writers, a term better discarded. As stated before the patient suffering from a true anginal seizure while in obvious distress is too concerned with the attack to wish or ask for sympathy, in fact, he is often remarkably quiet, while the subject of false angina presents exactly the opposite picture, his voluble description of his attack at once suggesting a neurotic background as a basis for his complaints.

The same type of patient complains of apical or precordial distress after

any psychic trauma grief, worry, surprise, even extreme pleasure Here the pain is rarely substernal or referred These patients both in military and civil life demand considerable attention They have been described under many names, probably neuro-circulatory asthenia or effort syndrome is the best

There is another type of precordial pain which has been frequently classed with the neuroses and certainly presents the general picture of a neurosis, but which is truly toxic in origin I refer to the dull ache, occasionally severe pain, noted by those who have become sensitized to tobacco, tea and coffee This pain is rarely reflected, lasts for hours, but is not incapacitating, at no time does the patient appear ill Complete withdrawal of the excitant is followed by complete relief, likewise, only slight exposure in those sensitized is sufficient to cause recurrence of the pain

DIFFERENTIAL DIAGNOSIS

Concerning the differentiation of those non-cardiac, but true disease entities with which coronary artery disease may be confused, enough has been said The anemias, hypoglycemias, valve and aortic ruptures, surgical abdomens, pulmonary conditions, and so forth, while a cause of temporary diagnostic embarrassment, are usually susceptible of differentiation after careful investigation, but after these are excluded there remain the larger numbers of either true instances of mild to severe cases of angina pectoris and coronary thrombosis, or a probably larger number of these cases of "false angina" Too great reliance cannot be placed upon the *angor animi* or sense of impending dissolution so strongly stressed by early writers This is in part dependent upon the psychic pattern of the individual, although there is a peculiar indescribable sensation associated with some anginal seizures which is not entirely dependent upon the severity of the pain As indicated before, probably the most conclusive evidence is the appearance of the patient during the attack In angina pectoris it is a rare experience for the physician to observe the attack, and the description of the lay observer is not too dependable

Standardized exercise tests which are both safe and yet sufficient to precipitate attacks of true angina pectoris have been introduced These tests offer an opportunity for careful observation³⁹ during an attack brought on in the office or hospital, and for observations as to results of therapy At least in those cases in which physical effort is the major factor, this method should prove a valuable means of differentiation from the false anginas

The hysterical patient can with ease and abandon present for anyone interested an excellent simulation of an anginal attack While it is true that organic heart disease may co-exist with a cardiac neurosis, this is not usually the case In general, it may be stated that evidence of organic heart disease, as enlargement, enfeebled heart sounds (in absence of a pulmonary or pleural cause for the same), persistent hypertension, or any electrocardio-

graphic evidence of coronary vessel or heart muscle disease, is acceptable confirmatory evidence of coronary disease, angina pectoris, or thrombosis when the clinical aspects suggest one of these conditions. The converse unfortunately is not quite true in the case of angina pectoris, for more than occasionally one will encounter a patient with the typical anginal syndrome in whom there is no demonstrable clinical, roentgen-ray or electrocardiographic evidence of heart change. Rarely these patients die without ever presenting any further evidence. In this group the final opinion is only arrived at after the elimination of all other possibilities. Sometimes only a sudden death establishes proof of organic disease.

ANGINA PECTORIS AND PERNICIOUS ANEMIA (OLD TERMINOLOGY), A RÉSUMÉ OF THE LITERATURE, WITH A CASE REPORT

By HUGH STALKER, M D , *Detroit, Michigan*

HERRICK and Nuzum¹ in 1918, were the first to describe cases of pernicious anemia with symptoms of angina pectoris. They found four such in a group of 200 cases of primary anemias. Three of these patients died, one of anginal seizure. On none was a necropsy obtained. In 1927 Herrick² added two cases to his original group. He further stated that a very careful search of current literature during the previous nine years bore him out as to the relative infrequency of this syndrome.

Hunter,³ Evans,⁴ Sturgis,⁵ Levine,⁶ Conners,⁷ Elliott,⁸ Beach,⁹ Smith,¹⁰ Donald,¹¹ and Colvin¹² each told of but a single case, while others quoted from larger statistics. Reid¹³ in 1923 reviewed the postmortem records of cases of pernicious anemia at the Boston City Hospital from 1916 to 1921 and found 11 cases which presented cardiac aspects. Bullrich^{14, 15} of Buenos Aires has been widely quoted as having presented seven cases of this syndrome, but on a careful reading of his two papers, it would seem that only one of his cases might be pernicious anemia. Carey Coombs¹⁶ in 1926 wrote that eight of 36 patients with pernicious anemia, all of whom he had personally observed, suffered from cardiac pain. Wilkinson¹⁷ in a study of 370 cases of pernicious anemia found three cases with symptoms of angina or coronary thrombosis. Keefe and Resnik,¹⁸ Portei,¹⁹ Pickering and Wayne,²⁰ Hochrein and Matthes,²¹ Paschkis,²² Bloch,²³ Zimmerman,^{24, 25} Reichel²⁶ in large series of pernicious anemia cases found comparatively few with anginal symptoms. There have been no cases of this syndrome at Harper Hospital in the past nine years and, in the anemia clinic in 1935, 43 cases of pernicious anemia were diagnosed and treated.

Herrick¹ in his first paper assumed that blood of poor quality going through somewhat narrowed coronary arteries might favor on slight provocation the development of an anginal attack. On observing patients with severe anemia he was frequently impressed with the remarkable degree of circulatory efficiency that was maintained. From this and other papers quoted, the consensus of opinion might be stated in the following quotation of Levine,⁶ "Even with one-twelfth of the normal number of red blood cells, I do not believe that the anemia would initiate an attack of angina without some background of coronary disease." Many have reported improvement and often complete cessation of anginal attacks following transfusion, and, more recently, anti-anemia therapy. White²⁷ stated "although it is the anemia and not the heart trouble that has usually been responsible for death, congestive failure and angina pectoris have been seen in rare cases." Re-

* Received for publication May 15, 1936

cently he told me he had seen a few cases with this syndrome and felt that the angina was due primarily to some coronary sclerosis or even spasm as described by Leary

But on the other hand Cabot²⁸ wrote of three cases of intense and typical angina associated with pernicious anemia and without coronary change. One showed a moderate sclerosis, the others none. To quote him, "Such cases certainly make us skeptical of any etiology wholly on organic and permanent changes either in the coronaries or in the aorta." Willius and Giffin²⁹ reviewed the records of 1560 cases of pernicious anemia and found but 43 (2.7 per cent) with symptoms of angina. Their conclusions were that the anginal syndrome in pernicious anemia is due to anoxemia of the myocardium and not to coronary or aortic sclerosis.

AGE AND SEX

White²⁷ stated that men presented anginal symptoms three times as often as women and that three-quarters of the cases of angina were past 50 years. Lewis³⁰ gave 45 years as the average age, Zimmerman in his series found that women had angina more frequently than men, and that the average age of patients with angina was 57.3 years, while for patients who presented the syndrome of angina pectoris and pernicious anemia the average age was 60.1 years. Lee and Minot³¹ stated that they had seen more men than women with pernicious anemia and that their ages ranged between 40 and 55 years. Schleicher³² quoted 53.7 years as the average age of patients in his group of pernicious anemia.

PHYSIOLOGY

In 1922 Fahr and Ronzone³³ studied a case of pernicious anemia with a hemoglobin of 12 per cent, 1,560,000 erythrocytes, and an oxygen carrying capacity of only 2.2 c.c. per 100 c.c. of blood (normal is 5.5 c.c.). The minute volume of the blood was increased proportionately. There was no dyspnea, no cyanosis, no increased pulse rate, and a normal basal metabolism or rate of oxygen consumption. A necropsy revealed a dilated heart with moderate increase in the thickness of the ventricular musculature. Their conclusions were that in severe anemias, the increased minute volume, due largely to lowered blood viscosity was the outstanding compensatory mechanism for loss of oxygen carrying power of the blood. The pathologic changes in the heart muscle in pernicious anemia might well be due to lack of oxygen as the coronary circulation was taxed to the upper limit and was comparable to that in strenuous work. It is well recognized that profound circulatory changes may occur in anemia, Liljestrand and Stenstrom,³⁴ and Richards and Strauss³⁵ have shown that the cardiac output is increased in anemia, Dautrebande³⁶ found a 300 per cent increase in cardiac output at a hemoglobin concentration of 20 per cent, with a return to normal value when the hemoglobin concentration rose above 50 per cent. Thus he found

over several months as long as the hemoglobin was above 50 per cent Kisch³⁷ thought it was probable that a deficiency of the capillarization of the myocardium was an important factor in the development of the attacks of cardiac pain. Rothschild and Kissin³⁸ showed that in eight of 11 patients who suffered from angina pectoris, pain could be induced by breathing air deficient in oxygen and ascribed the pain to the direct effect on the myocardium. Dietrich and Schwiegl³⁹ thought that during an attack of angina pectoris there existed an ischemia of the cardiac muscle and that not only the changes in the electrocardiogram but also the pains were a result of this ischemia.

Lewis⁴⁰ from his experiments upon human voluntary muscle inferred that myocardial anoxemia was not the direct cause of anginal pain. He felt that such pain must have a physico-chemical basis and must be attributable to a change in the conditions in the tissue spaces outside the muscle fiber. On the basis of this view it follows that the avoidance of pain in muscle depends upon adequate irrigation with blood, which removes the pain-producing substance, thereby preventing its accumulation in sufficient amount to cause pain.

Although the reaction of heart rate and blood pressure to exercise is usually altered in anemia and such alterations may contribute to the development of anginal pains, it may be assumed that the precipitating factor in the production of anginal pain in anemia is the lack of oxygen, which acts by producing a physico-chemical state that is the concomitant of pain. The anemic patient may be stopped by one of four events—breathlessness, giddiness, angina, or intermittent claudication. If the coronary arteries are diseased the relevant event will be angina, if they are not, then it will probably be breathlessness or giddiness. But in some patients, for a reason that is not yet at all clear, breathlessness and giddiness seem to be less easily induced and exercise may be carried on to the point of producing angina pectoris even in the absence of local disease of the vessels.

PATHOLOGY

The most constant finding has been fatty degeneration of the myocardium. This change in the heart muscle is found in a variety of conditions and seems not to be inconsistent with perfect health. The fat is not due to a degeneration or breaking down of the muscle fibers, but is brought by the blood stream and deposited in the heart, and evidence is lacking that the myocardium is impaired thereby. In Reid's¹⁸ cases enlargement of the heart of a degree that should be recognized clinically was not found, in six cases the actual weights of the hearts were between 240 and 340 grams, and in five between 300 and 400 grams. The hearts in this group of 11 necropsies showed the myocardium microscopically to be abnormal in only two cases. In these there were areas of necrosis of the fibers. In four instances the endocardium, especially on the papillary muscles, was mottled

and streaked with yellow, the so-called tigroid appearance. The epicardial fat was recorded as moderately increased in four cases and greatly so in two; otherwise these hearts were normal, save for moderate sclerosis of the coronary arteries in four, of the mitral valves in five and of the aortic cusps in two. Willius and Giffin²⁰ reported a necropsy on a woman of 55 with this syndrome. The heart was small and apparently normal except for fatty changes in the myocardium. Coombs¹⁶ had one postmortem only, it showed a diffuse atheroma of the aorta. The coronary arteries were not mentioned. At necropsy Elliott⁸ found in his case that the tigroid markings usually seen in cases of pernicious anemia were absent. By microscopic section there was no evidence of coronary or myocardial disease. Two of Reichel's²⁶ three patients came to necropsy. The heart of one had dilated chambers, normal aorta and valvular apparatus, and, microscopically, vacuolization of the muscle bundles. The second patient had arteriosclerosis of the aorta, fatty change of the left ventricle, and an area of myomalacia. The coronary arteries were not specifically mentioned in either instance but the finding of myomalacia in the second suggests the presence of coronary disease. Four cases in Zimmerman's^{24, 25} series of pernicious anemia came to autopsy—two with angina and two without. All four showed the same thing—complete calcification of the coronaries. There are at least five cases described (Cabot,²⁸ Willius and Giffin,²⁰ and Elliott⁸) in which no changes in the coronary vessels were found postmortem.

ELECTROCARDIOGRAMS

Pickering and Wayne²⁰ examined the electrocardiograms of 10 of their cases of severe anemia. In one with angina pectoris which persisted after cure of the anemia, there was a left ventricular preponderance. In two cases, the P-R interval was longer than normal when the patient was anemic and within normal limits after cure of the anemia. In the first case the P-R interval was 0.265 second when the hemoglobin content of the blood was 35 per cent and fell to 0.19 second when the hemoglobin content was 97 per cent. In the second case the corresponding figures were 0.205 second at a hemoglobin content of 38 per cent and 0.145 second at a hemoglobin content of 110 per cent. In the other cases no abnormality was noted during the anemic state. Curves taken immediately after the end of exercise in three anemic cases showed no changes in the shape of the R-T segment or any changes other than those directly attributable to exercise alone.

Reid¹³ found the QRS-T interval of normal duration and concluded the increased output of the heart was not accomplished by a lengthening of the ventricular systole. On examining 20 tracings he found nothing that might be considered of diagnostic value or as peculiar to pernicious anemia. Porter¹⁰ found in one case a slight left axis deviation and an isoelectric T-wave in Lead I. Reid,¹³ Willius and Giffin,²⁰ Hochrein and Matthes,²¹ Bloch,²³ and Smith⁴¹ felt that there was no typical electrocardiographic picture.

CASE REPORT

In May 1931, the patient, a male, 53 years of age, while at work suffered a severe, crushing, oppressive pain under the sternum. Previous to this he had experienced only an occasional mild attack. He was taken home and a physician was called who gave a small amount of digitalis, but no narcotic. The pain lasted about 24 hours, during which time the patient expectorated some pink sputum. Following this he remained in bed for two weeks and, after a few days' convalescence, returned to his work. For the next two months he was symptom free. Then he consulted another physician who treated him for diabetes although sugar was found in only one specimen. For one and a half years he had no severe attacks but everything he did was done with effort. His appetite was poor. During this period he was seen every two months by his physician.

In August 1933, the patient had a severe attack and another doctor was called. Following the immediate treatment he gave him hypodermic injections of iron and arsenic for anemia two to three times a week for eight months. From that time on he had frequent substernal pains. During February and March 1934 while working at night the patient had many severe attacks of pain radiating down both arms which never lasted more than 15 minutes. These attacks of pain came on at any time, after eating, or while sitting still, and were always accompanied by violent attacks of coughing. He also complained of frequency of urination. About this time nocturnal dyspnea began. In April 1934, his physician ordered an electrocardiogram which was reported as normal and hence he gave a favorable prognosis. Because of no improvement in his condition the patient sought another doctor and in August 1934 he had another electrocardiogram which showed left axis deviation and ventricular extrasystoles. For his pain he was never given nitroglycerine but always morphine sulphate by hypodermic injection which was invariably followed by nausea and vomiting. Still another physician saw him and suggested that he might have cancer.

The patient was first seen by the writer, following a severe attack of pain under the upper sternum September 15, 1934. A few additional items were added to his history. The pain even awakened him at night and frequently lasted for one and a half hours. It was very sharp, except occasionally when it diminished to a duller discomfort. Frequently it was located near the epigastrium and seemed to follow a rotary motion. Occasionally it spread out in oblong fashion and his arms pained terribly at the same time. Sometimes it was relieved by coffee.

Usually his bowels were regular. There had been some loss of weight, perhaps 20 pounds. Sometimes there was noted a slight edema of ankles and feet. He felt very weak, his appetite was poor, he ate no meat. He had been on digitalis and euphylline but had stopped taking them because of nausea.

He had never suffered with sore tongue, digestive disturbance, paresthesias, or anesthetics of fingers or toes.

The patient's past history was irrelevant except for a so-called attack of gall stones 11 years previous, with no recurrence. The patient denied venereal disease.

In the family history it was noted that his father had died at 64 "instantly, after working in field." One brother died of angina at 68. One sister, living, has angina at 69.

Physical Examination The patient appeared moderately well-developed, poorly nourished, and much older than his stated age. His height was five feet six inches. His hair was streaked with gray, the skin was rather sallow, flabby, and somewhat dehydrated, the eyes showed an arcus senilis, and the sclerae were slightly yellow, the tongue was not noticeably smooth, the papillae were of moderate size.

The heart was definitely enlarged both to left and right. There was an accentuation of the first sound, a gallop rhythm, a systolic and a rumbling diastolic

murmur at the apex, and also a very loud diastolic murmur at the aortic area and along the left border of the sternum. The pulmonic second sound equaled the aortic second. The pulse was 84. There was noticeable pulsation of the neck vessels. Blood pressure was 120 over 50 millimeters of mercury. The liver and spleen were not felt. The knee jerks were active and equal.

Laboratory Findings Urine examinations were essentially negative. The Kahn test was negative. Hemoglobin 53 per cent (Sahli), red blood cells 1,560,000 per cu mm, color index 1.7, mean diameter 8.3, white blood cells 4,500 per cu mm, stab polymorphonuclears 5 per cent, segmented polys 47 per cent, lymphocytes 41 per cent, eosinophiles 1 per cent, monocytes 5 per cent, basophiles 1 per cent. There were two 7 lobed polymorphonuclear neutrophils, one 3 lobed eosinophile, and one nucleated red blood cell seen, marked anisocytosis, poikilocytosis, many slightly oval forms, some achromia, some cells well-filled with hemoglobin.

A diagnosis was made of hyperchromic macrocytic anemia, angina pectoris, and aortic regurgitation and stenosis.

Treatment Because of marked dyspnea the patient was digitalized. He was also given ephylline grains $1\frac{1}{2}$ three times a day, frequent high caloric feedings, nitroglycerine grains $1/150$ as needed for pain, small amounts of whiskey and brandy, and two cubic centimeters of Parke Davis liver extract parenterally daily.

The patient had a bad cold twice, and because the increase of red blood cells seemed at times to be very slow, the liver extract was increased to four and for a short time to six cubic centimeters daily, as it is known that any factor, such as constipation, cold or infection, is enough to inhibit hematopoiesis. Once, following the injection of 6 cc, the patient experienced bulging of his ear drums and stated that there was palpitation of his heart. He felt weak and had to lie down as soon as he reached home. The symptoms lasted but a very short time.

The patient was always able to relieve his substernal pain with nitroglycerine and after one week, when the red blood count had reached 2,450,000 and the hemoglobin 71 per cent, he rarely had an anginal attack unless he exerted himself more than normally. As will be noted the red blood cells reached 5,000,000 in a little less than three months.

Following the intravenous liver he took ventriculin and kept his red blood count at a normal level. He filled out, his weight increased 10 pounds, his appetite was tremendous, and his general well-being was that of a man on the road to recovery. But his heart always showed a very loud aortic diastolic murmur and to the end the aortic second sound remained louder than the pulmonic second. The patient had an occasional attack of cardiac asthma.

Because he felt so well, he returned to his work, which was very light, shortly after the first of January 1935. On the third day following his return to work, he had an unusually severe anginal seizure while carrying a very heavy bottle of water. Instead of dropping the bottle he held it while the attack lasted, this prevented his getting any nitroglycerine. From then on he went slowly down hill. His cardiac asthmatic attacks became almost continuous. He had an idiosyncrasy for morphine and pantopon, manifested by marked nausea and vomiting, but was definitely relieved from his cardiac asthmatic attacks, without after-effects, by dilaudid given hypodermically and occasionally by sodium bromide and chloral hydrate by rectum.

As his cardiac asthma increased in frequency until it was almost continuous, his anginal attacks almost ceased. At the same time his appetite decreased and he was unable to continue with ventriculin. He began to show edema of lungs, abdomen, and feet which finally reached his knees. This was relieved by frequent intravenous injections of 2 cc of salyrgan. He became semi-comatose March 22, 1935, and two days later died in his sleep.

Autopsy Permission to examine the heart only was given. The findings were

as follows Weight 760 grams, left ventricular wall 27 millimeters, right ventricular wall 12 millimeters Grossly there were well marked fatty areas in the myocardium and a "tiger lily" appearance, especially of the papillary muscles There was functional insufficiency of all valves No signs of cardiac infarction either old or recent were found The aorta and the aortic valve showed marked sclerosis and calcification, and the cusps could not approximate The openings to the coronary arteries were enlarged, but on cross section through the arteries themselves they were found solidly calcified, barely admitting the tip of a common pin

SUMMARY

A case of angina pectoris and hyperchromic macrocytic anemia (with aortic stenosis and regurgitation, coronary sclerosis, cardiac asthma, and an idiosyncrasy for morphine) has been presented with a resumé of the literature bearing particularly on this symptom complex It apparently is not a common syndrome The anginal pains were relieved as usual with nitroglycerine but were less frequent when the blood picture approximated the normal, or at least, improved when a higher blood count was obtained The theory has been propounded that anoxemia is a factor initiating angina, and it is conceivable that, in pernicious anemia, blood of poor quality might readily aid in the development, on slight provocation, of an anginal spell Because the age period of both of these diseases is approximately the same it may be a natural occurrence that they are found together in the same patient It was felt by one investigator that patients with anemia do not very often develop angina because of their general easy fatigue which causes them to stop short of the danger point But as most patients with pernicious anemia do not have angina, the anemia per se cannot be a primary cause

Again the pathologic changes in the heart muscle in pernicious anemia have been thought to be due to lack of oxygen from the fact that the coronary circulation is taxed to the upper limit, comparable to the effects of strenuous work In general the consensus of opinion has been that there were no diagnostic abnormalities in the electrocardiograms and what changes were noted could be traced to a coincident atherosclerosis

CONCLUSIONS

The writer presents a case of angina pectoris with pernicious anemia and reviews the slightly over one hundred similar cases in the literature As so few cases of this syndrome have failed to show sclerosis of the coronary arteries, one may safely assume that most anginal pains in this symptom-complex result from anoxemia of the myocardium due to sclerosed coronary arteries But when in addition the blood is deficient in adequate oxygen carrying power, the functional capacity of the myocardium is still further diminished and angina occurs more readily Hence the incidence of cardiac pain in atherosclerosis with pernicious anemia is higher than in atherosclerosis alone

BODILY BUILD AND HEREDITY IN CORONARY THROMBOSIS

By GRACE A. GOLDSMITH, M.D., and FREDRICK A. WILLIUS, M.D.,
F.A.C.P., *Rochester, Minnesota*

THE importance of habitus in its association with certain pathologic states has been the subject of considerable discussion in recent years. The coexistence of obesity and hypertension has often been emphasized. It has been our clinical impression that many individuals who have coronary thrombosis are overweight, but no adequate statistics are available regarding this question. The tendency for abnormal degrees of arteriosclerosis and their premature manifestation to occur with unusual regularity in certain families, and the proclivity of angina pectoris to be a familial disease have been recognized for many years.

To investigate the importance of bodily build and heredity in coronary thrombosis, 300 cases observed in the past few years at The Mayo Clinic have been reviewed. The diagnosis of coronary thrombosis was confirmed in these cases by postmortem findings, characteristic changes in the electrocardiogram, or a typical history of this condition at some time prior to our examination plus residual electrocardiographic changes. This group of individuals consisted of 272 men and 28 women who were between 40 and 80 years of age, 118, or 39 per cent of these patients, were between the ages of 50 and 59 years. In each case the following data were obtained: age, height, average weight prior to the patient's admission to the clinic, weight at the time of examination, detailed characteristics of bodily build whenever stated, and family history, including, whenever possible, the age and cause of death of parents and siblings. The presence or absence of cardiovascular renal disease in the family was noted.

Having obtained the present weight of each individual, this was compared with the average weight for the age and height, as given by the insurance standards. The weight of each individual has been expressed as a percentage difference from the standard weight according to sex, age and height. Figure 1 shows the distribution of weights expressed in these terms for the entire group studied, using the observed weight of the individual at the time of his examination at the Clinic. The mean deviation was +1.8 per cent. The weight varied from -42.5 per cent of standard to +47.5 per cent. The number of patients who were overweight slightly exceeded those who were underweight, 51 (17 per cent) were more than 15 per cent overweight, while 39 (13 per cent) were more than 15 per cent underweight. The weight of 13 patients exceeded the average weight by more than 30 per cent, while the weight of only one was more than 30 per cent less than the average.

* Received for publication November 3, 1936.

From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

FIG 1 Distribution of weights of patients at time of examination at the Clinic, expressed in terms of deviation from standard weight according to sex, age and height

weight As previously stated, the weights used in plotting the graph in figure 1 were those determined at the time of examination at the Clinic. Many patients were very ill and had lost weight. It seemed appropriate to use the average weight of the patient prior to his illness instead of the weight as determined at the time of examination, and to compare the former with the standard weight. The results of this study are shown in figure 2. The

FIG 2 Distribution of weights of patients before illness, expressed in terms of deviation from standard weight according to sex, age and height

mean deviation from the average was in this instance $+6.7$ per cent. Only seven individuals gave a history of an average weight 20 per cent or more below the standard, while 55 individuals had an average weight of more than 20 per cent above the average. Thirty-seven individuals (12 per cent) were more than 10 per cent underweight while 123 individuals (41 per cent) were more than 10 per cent overweight, as determined by the standards used.

Figure 3 gives a more detailed analysis of the problem, the total group of women and the men in each age group were studied separately, except the five patients who were between 30 and 39 years of age, who were too

FIG 3 Distribution of weights of patients before illness, expressed in terms of deviation from standard weight for men and women separately and for specific ages for the men

few to be significant. The weight used was that which the individual described as his normal average weight prior to the onset of the presenting illness. The tendency to overweight is evident among patients of all ages except among the men who were more than 70 years of age. The findings obtained in this last group are probably partly the result of inadequate standards for this age. The men who were between 50 and 70 years of age and all of the women showed a mean deviation of more than +7.5 per cent from the average.

Details of habitus aside from a tendency to obesity, were meager. A number of individuals were described as plethoric, some were of the short stocky type and had thick necks, others were of large powerful build. A ruddy complexion or flushed face was often noted as was the fact that the individuals were often nervous and high-strung. In contrast to this a num-

ber of persons were obviously very ill, pale, sallow, or cyanotic, and revealed evidence of recent loss of weight. Apparently all types of bodily build were represented and the data were inadequate to determine statistically the predominance of any one type.

There was a family history of cardiovascular renal disease in 165 (55 per cent) of the 300 cases. Fifty-seven (35 per cent) of the patients said that two or more members of their immediate family (parents or siblings) had some type of cardiovascular disease. Eighteen patients said that both parents had died of heart disease or cerebral hemorrhage. The cause of death of one of the parents, or the cause of the death of siblings, was given as cerebral hemorrhage in 52, coronary thrombosis in 14, heart disease (type not stated) in 52, hypertension in five, dropsy in nine, nephritis in 23, and uremia in three cases, respectively. It seemed of interest to determine whether individuals who gave family histories of cardiovascular disease died at an earlier age than did their parents. Such data were available in 88 cases. In 70 cases, only one parent had died of this type of disease. It was discovered that 30 patients died at a younger age and 12 at a more advanced age than had the affected parent, while 28 were still living but had not yet attained the age at which the parent had died. In the 18 cases in which both parents had succumbed to cardiovascular disease, three patients died at a younger age than had either parent, seven died at a younger age than had one parent, six, who are still living, have not attained the age reached by the parents, and in two cases the age at which death of the parents occurred was unknown.

In the series of 165 cases in which there was a history of cardiovascular renal disease among other members of the family, 83 of the patients have died. The average age of the patients at the time of death was 59.2 years. Of the 135 patients who did not give any history of cardiovascular disease in the family, 50 have died, their average age at the time of death was 60.1 years. No conclusive information is gleaned from these figures as in both groups of cases the age of the patients at the time of death was apparently the same, although fewer deaths occurred in the group in which there was no family history of cardiovascular renal disease. The evidence presented suggests that the presence of cardiovascular disease in the family diminishes the chances of longevity. The high familial incidence of cardiovascular renal disease in this series of cases supports the view that there is an hereditary tendency for these pathologic conditions to develop.

In this group of 300 cases, there were 83 patients (28 per cent) who had hypertension. It was thought that the habitus in this group might differ from that of the group in which the patients did not have high blood pressure. Table 1 shows that in this series the weight of 59 per cent of the patients who had hypertension was at least 5 per cent more than the average weight for height and age according to the standards used, while only 48.85

per cent of those who did not have hypertension were more than 5 per cent overweight. Similarly, the group of patients who had hypertension included only 16 per cent of patients who were more than 5 per cent underweight, while the group of patients who did not have hypertension included 27 per cent of patients who were more than 5 per cent underweight. It is thus evident that the patients who had hypertension were inclined to be more obese than were those who had a normal blood pressure.

TABLE I

Relation of Weight of Patient to Family History and Value for the Blood Pressure

	Pa- tients	Percentage of patients who were more than 5 per cent under- weight	Percentage of patients whose weight was normal (+5 pounds to -5 pounds)	Percentage of patients who were more than 5 per cent over- weight
Family history of cardiovascular disease	165	23.03	24.84	52.13
No family history of cardiovascular disease	135	25.19	23.70	51.11
Hypertension present	83	15.66	25.30	59.04
Normal value for blood pressure	217	27.19	23.96	48.85

Table 1 also shows the percentage of individuals who were overweight or underweight and who did or did not give a family history of cardiovascular disease. Slightly more than 50 per cent of the patients in both groups were overweight by 5 per cent or more, as compared to the standards.

COMMENT

While the habitus of the patient does not appear to be of outstanding importance in the predisposition to coronary thrombosis, the occurrence of overweight in more than half of the cases is not without significance. This observation, moreover, is another indictment against obesity in general.

The data in this study do not permit the determination of conclusive facts regarding the hereditary tendencies to coronary disease, although the more than casual repetition of cardiovascular renal diseases in certain families is of interest and undoubtedly is of importance. The fact that it is virtually impossible to obtain reliable data regarding the causes of death, even among the patient's grandparents, to say nothing of preceding ancestors, makes the establishment of a hereditary continuity almost impossible, except in rare instances.

Nevertheless, clinical contacts with many patients over long periods of time create an impression that hereditary influences play a much more important rôle in coronary disease than is generally admitted.

SUMMARY

A study of the habitus of 300 individuals who had coronary thrombosis revealed a mean deviation of ± 6.7 per cent from the average weight for height and age. The individuals who had hypertension tended to be more overweight than did those who had a normal blood pressure. There was a family history of cardiovascular renal disease in 165 of the 300 cases. Familial predisposition to cardiovascular disease showed no correlation with the degree of obesity.

THE EFFECTIVENESS OF TRICHLORETHYLENE IN PREVENTING ATTACKS OF ANGINA PECTORIS¹

By WILLIAM S. LOVE, JR., M.D., F.A.C.P., *Baltimore, Maryland*

TRICHLORETHYLENE has been used for some time in the treatment of trigeminal neuralgia. Its therapeutic activity in regard to this condition has been discussed by Glaser,^{1,2} and an extensive bibliography of its use for this purpose is given in his papers. It has also been used as an anodyne in dental procedures and for dental pain^{3,4} and with some success as an anesthetic for operations upon the face⁵. In a conversation with Dr. David Bryce in which the discussion turned upon angina pectoris, it was suggested by him that trichlorethylene might prove of use in preventing such attacks. The following investigations were then undertaken:

CERTAIN PHARMACOLOGICAL ACTIONS OF TRICHLORETHYLENE

After exhibition of this preparation had apparently benefited certain patients with angina pectoris, Dr. John C. Krantz, Jr., of the Department of Pharmacology of the University of Maryland, kindly undertook the study of certain questions in regard to the pharmacological action of this drug^{6,7,8}. His observations indicate that:

- 1 Trichlorethylene causes a constriction of the perfused vessels of the frog
- 2 It does not influence the oxygen consumption of rats
- 3 It has an irregular effect upon the coronary flow of the dog, at times increasing and at times diminishing this flow
- 4 It decreases the blood pressure and slows the heart rate in dogs
- 5 When applied directly to the sciatic nerve it fails to block the blood pressure and respiratory responses to faradization

He concludes that the drug probably causes hypalgesia by depressing the basal ganglia and perhaps produces a relaxation of the vessels of the splanchnic area while causing a peripheral vasoconstriction.

Pharmacological Actions of Trichlorethylene on Human Subjects In 27 patients with cardiovascular disease of some type, under treatment with this drug, there were 13 with systolic blood pressures of over 150 mm of mercury and diastolic levels of over 100. In this group of hypertensive patients, taking trichlorethylene by inhalation in 1 c.c. doses thrice daily, the systolic pressure fell from 20 to 30 mm. in four, and 40 or more mm. in two. The shortest period in which such a drop is known to have occurred

* Received for publication August 1, 1936. From the Department of Medicine, University of Maryland.

The author is indebted to the Calco Chemical Company, Bound Brook, New Jersey, for supplying much of the trichlorethylene used in carrying out this investigation.

is one week, the longest six weeks. One patient showed a rise of 10 mm. The systolic pressure fell 20 mm in one patient not classified as hypertensive. Three normal individuals with normal blood pressures inhaled 1 c c thrice daily for three weeks. In two of these there was no significant change in the blood pressure. One consistently had an average fall of 20 mm in systolic and diastolic pressure, beginning during the inhalation and lasting for about 20 minutes. There was no permanent lowering of the pressure in this individual. Thus in 31 individuals subjected to the inhalation of 1 c c of trichlorethylene three times daily, there was an immediate and transient fall in blood pressure in only one, and in seven a significant fall occurring a week or longer after the inhalations were begun. It is probably of significance that six of these seven individuals suffered from hypertension, and that six of thirteen hypertensives presented such a reaction.

The following experiment indicates that such decreases in blood pressure are not associated with any marked impairment in the conductivity of reflex pathways.

W. M., aged 48 (case 24), known hypertensive for at least three years. Blood pressure at beginning of treatment, 190/130, two weeks later, 175/105, six weeks after initiation of treatment, 130/85.

Blood Pressure before test 135/85	Left hand immersed in ice water Blood Pressure in		
	30 seconds	1 min	2 min
	170/100	190/110	210/140

Skin temperatures have been determined by a thermopile before, immediately after, and after continued inhalation of trichlorethylene in three normal individuals. In two there has been no change in temperature and in one there has been a slight drop. This suggests that in the dosage used there occurs neither a marked peripheral vasodilator nor vasoconstrictor response to trichlorethylene in man.

There is not sufficient evidence at this time upon which to base an explanation of a reduction in blood pressure following the continued use of trichlorethylene. It is perhaps due to the sedative action of the drug.

The pulse rate has not been significantly altered in most individuals. A few have shown a transient rise of as much as 20 beats per minute. This is contrary to the results obtained by Krantz and his co-workers on dogs and is probably to be attributed to psychic reactions.

TOXICOLOGY

Joachimoglu⁹ considered the drug harmless. Krantz and his co-workers⁸ conclude that repeated anesthetizing of rats did not markedly influence their growth curves or subsequently lead to important pathological changes in their viscera. Eichert¹⁰ reports two cases of toxic psychoses following therapeutic use of trichlorethylene and quotes from Zulkis one of addiction to the drug with toxic effects. In all three cases gross overdosage had been

voluntarily taken by the patients. All recovered without demonstrable ill after-effects. Taylor¹¹ reports that following daily six hour inhalation exposures to trichlorethylene, rats survived six months when concentrations of 0.2 per cent or lower were used. Pathological examination at the end of the experimental period revealed no signs of degeneration in any organ. A concentration of 0.3 per cent proved too high, only two of six rats surviving six months.

No evidence of toxicity has occurred in any of the 28 cases of this series. One patient has been taking trichlorethylene from time to time for three years, and during the first year used it almost daily.

Alice Hamilton¹² discusses 284 cases of industrial poisoning supposedly due to trichlorethylene. In this group there were 26 deaths. While there is no decisive evidence on this point, it seems likely that such cases of industrial poisoning are due to substances other than pure trichlorethylene. Trichlorethylene on contact with air and light may form decomposition products among which phosgene has been identified.

METHOD OF TREATMENT

While some observations have been made upon the usefulness of this drug in relieving immediate attacks of angina pectoris and the pain of coronary thrombosis, the primary purpose has been to discover if anginal seizures would be prevented or diminished in frequency and severity by this drug.

Twenty-seven patients have been treated as follows: from two to four, usually three, inhalations of trichlorethylene have been given daily. Sealed frangible glass ampoules of one cubic centimeter are crushed in a handkerchief. The first inhalation has always been taken in the presence of a physician so that the immediate effect might be noted, and the patient reassured, if alarmed. Thereafter, patients are advised to take the drug either while reclining or sitting in an easy chair, for marked lightheadedness often occurs, and occasionally there is a brief loss of consciousness. The treatment is continued as above for three weeks. If no therapeutic effect has been achieved in this time, the use of trichlorethylene has been discontinued, and the method considered ineffective. Should the treatment prove effective, the number of inhalations is reduced in each individual to the minimum consistent with an adequate relief of symptoms.

THE EFFECTS PRODUCED BY THE INHALATION OF ONE C C OF TRICHLORETHYLENE THRICE DAILY, OTHER THAN UPON CARDIAC PAIN

When inhaled this drug is irritating to the mucous membranes of the respiratory tract and a sensation of burning commonly occurs in the nose, and the patient usually coughs, but not violently. Within a few seconds after the inhalation is started the patient complains of lightheadedness and

in about one-half this effect is marked. Such lightheadedness lasts only a few moments and leaves the patient mentally clear. Three patients of 27 lost consciousness for periods lasting from two to five minutes. Headaches subsequent to its use have not been noted. Five patients described a feeling of marked well-being, amounting to a mild euphoria. When the patient has been nervous and irritable and sleep has been restless, well-marked sedation, loss of irritability and quiet sleep have usually followed the exhibition of this drug. This, however, has not been accompanied by any dulling of the mentality of sufficient degree to be noticed by the patients or manifested by any loss of ability to perform their usual work. One patient became so alarmed at temporary loss of consciousness that this mode of therapy had to be discontinued.

EFFECT OF TRICHLORETHYLENE UPON THE PAIN ACCOMPANYING CORONARY THROMBOSIS

Six patients have been given trichlorethylene during immediate attacks of pain due to coronary thrombosis. Cases 1, 2 and 3 received the drug within 12 hours of the onset of such pain, and case 4 had been started the preceding day in the hope of preventing paroxysms of hypertension associated with anginal pain. In this last case thrombosis occurred after three inhalations. The patient lived for three days and trichlorethylene had no appreciable effect upon the pain. Cases 1 and 2 received immediate relief from pain. In case 1 the intervals between recurrence of pain were very irregular, and if additional trichlorethylene were inhaled at the beginning of the pain it was aborted within a few minutes. Case 2 lost consciousness for about five minutes after each inhalation, and freedom from pain was obtained for about one hour. Morphine proved more satisfactory for controlling pain in this patient who died on the seventh day of her illness. Case 3 received no relief with morphine in $\frac{1}{2}$ grain doses given twice before admission to the hospital. A single inhalation of trichlorethylene gave marked relief in a few minutes and the inhalation was immediately repeated, complete relief from pain being then obtained. Freedom from pain lasted from one-half to three-quarters of an hour, and it did not again become intense for about three hours. Inhalations were ordered for this patient at three hourly intervals and he was permitted to receive additional inhalations on request. After 72 hours only occasional inhalations were taken.

Cases 5 and 6 were seen five and seven days respectively after coronary thrombosis had occurred. As noted in the case histories, striking relief followed the exhibition of trichlorethylene to both of these patients. However, it is well known that the pain and distress of coronary thrombosis tend gradually to become ameliorated at varying times after their onset. One could not say in case 5 that this had not happened in the natural course of events. Case 6 offers more positive evidence of the rôle played by trichlorethylene in as much as morphine had previously failed to give relief up to

the moment the inhalations were started. In less than 12 hours after the initial inhalation this patient had his first restful night and sleep.

Thus in three of four cases seen within 12 hours of the onset of coronary thrombosis trichlorethylene afforded relief from pain, proving more useful than morphia in one case and less so in one case. In case 1 morphia was not used. In one case trichlorethylene was ineffective. In two more cases relief of pain followed the exhibition of this drug but because of the length of time elapsing from the occurrence of the thrombosis to the initiation of inhalation treatment, disappearance of the pain cannot with certainty be attributed to this treatment. It is possible that trichlorethylene was more effective than morphia in one of these cases. When successfully used, it had the advantage over morphia of not causing constipation.

Case 1 White male, aged 54. Hypertensive arteriosclerotic cardiovascular disease. Angina pectoris followed in six months by coronary thrombosis. Continued frequent recurrence of pain, severe, while in bed. Blood pressure very variable, before attack averaged 200 millimeters of mercury systolic and 120 diastolic, after attack fell to 140 systolic and 100 diastolic then rose to 180 systolic and 120 diastolic with paroxysmal elevations as high as 260 systolic and 160 diastolic. Slight relief with theobromine. Pain often aborted by single inhalation of trichlorethylene, and inhalations given three times a day prevented pain. The blood pressure became stabilized at about 175 systolic and 110 diastolic. The patient has been under observation two years, during which time there have been two apoplectic seizures. Cardiac pain recurs periodically and is relieved and prevented by trichlorethylene. Electrocardiogram just before attack of thrombosis. Leads I and II show the coronary type curve, a record 16 months later shows no essential difference. This patient is a very high strung, irritable individual.

Case 2 White female, aged 49. Coronary thrombosis. Blood pressure, 90 systolic and 70 diastolic. Died on seventh day. Trichlorethylene gave temporary relief lasting for about one hour after each inhalation. This patient was unconscious for about five minutes after each inhalation. Morphia proved more satisfactory in this case.

Case 3 White male, aged 48. Acute coronary thrombosis preceded by anginal pain on exertion for four days. Leads I and chest lead type of acute coronary curve. Blood pressure on admission, 150 systolic and 110 diastolic, dropping to 80 systolic and 60 diastolic. Pain not relieved by morphia. Relieved by trichlorethylene completely for one-half hour after inhalation and pain ameliorated up to two or three hours.

Case 4 White male, aged 50. Arteriosclerotic cardiovascular disease. Paroxysmal hypertension with anginal pain. Coronary thrombosis—died third day after onset. Blood pressure 120 systolic and 95 diastolic, going to 180 systolic and 120 diastolic in attacks. Electrocardiogram before attack. Normal mechanism. Trichlorethylene started day before thrombosis and continued to death. No relief.

Case 5 White male, aged 52. Arteriosclerotic cardiovascular disease. Coronary thrombosis with pain persisting in attacks for one week while in bed. Blood pressure 110 systolic and 80 diastolic. Electrocardiogram none. Complete relief in 24 hours.

Case 6 White male, aged 71. Arteriosclerotic cardiovascular disease. Coronary thrombosis with persistent pain, nausea and vomiting, complete incapacity five days after attack. Blood pressure, 120 systolic and 90 diastolic (stated to have previously averaged 170 systolic and 100 diastolic). Complete relief of pain within

12 hours after exhibition of trichlorethylene, restful sleep Morphua in 1/8 grain doses had previously failed to give relief Trichlorethylene continued one week, no recurrence of pain after drug stopped

TRICHLORETHYLENE USED TO PREVENT ATTACKS OF ANGINA PECTORIS

Of the remaining 21 patients, 18 had either arteriosclerosis or arteriosclerosis and hypertension combined, there was one case of syphilitic aortitis, one case of chronic nephritis, and one case in which there was a history of hypertension not found at time of examination Of these patients nine gave a history of having had an attack of coronary thrombosis not more than two years previously The electrocardiogram was normal in one, of the coronary type in 10, presented definite deviations from normal in nine and was not recorded in one All of the above patients presented angina pectoris as a symptom of their disease Trichlorethylene was inhaled by these patients as a rule three times a day In these 21 patients anginal seizures were prevented completely by the inhalations in eight, they were definitely diminished in frequency and severity in eight and moderately diminished in one This last patient had syphilitic aortic insufficiency and was receiving antiluetic treatment This of course may account for the improvement that was observed Four patients received no benefit from the inhalations In seven patients it was noted that the pain recurred as severely as formerly whenever the inhalations were discontinued, the period of time elapsing before its recurrence varying from 24 hours to several weeks The period of time from the initiation of treatment to the cessation of symptoms varied considerably, no attacks occurring in some instances after the first inhalation, and in others the improvement being gradual—case 25 did not achieve his maximum improvement until six weeks after beginning the inhalations In one patient* this treatment gradually lost its effect as a preventative in two months, but still could be effectively used to relieve immediate severe attacks of angina pectoris

The exercise tolerance of these patients has only been directly tested in case 26 In this case it will be noted that there was a definite increase in the amount of exercise performed without pain The pain, however, was just as severe when it was finally induced All patients receiving benefit from the treatment could do more of ordinary activities than was possible before it was commenced, and where such statements are definite, they are noted in the case histories

I have no data for an adequate comparison of the effectiveness of trichlorethylene with that of other drugs used for the relief of angina pectoris The above studies have been directed toward determining its effectiveness in preventing such attacks However, it has been noted to be effective for

* Since offering these observations for publication, case 23 has reported that prevention of attacks no longer results from inhalation of trichlorethylene and that he has had to retire from business because of their frequent occurrence when under mental strain Therefore there are two patients who have reported that the original beneficial effect of trichlorethylene inhalations did not last

the former purpose in several cases in which other drugs have been used. Thus in case 20 amyl nitrite had at first afforded relief from pain, but later failed to do so, inhalations of trichlorethylene were then found effective.

Five patients other than those with coronary thrombosis obtained immediate relief from anginal seizures, three specifically note that no relief was obtained. However, it is my present impression that there is little likelihood of this drug proving as effective for the relief of the anginal attack as are other already accepted methods of treatment.

There is no evidence that this drug in any way effects a cure, symptoms usually return when its use is discontinued.

CASES OF ANGINA PECTORIS

Case 7 White male, aged 37. Neurotic personality. Anginal type of pain, tight, retrosternal, radiating to left arm, occurring on unusual exertion or after large meals. Blood pressure, 150 systolic and 105 diastolic. Electrocardiogram slurring of QRS, T_1 inversion, large Q_1 . Pain prevented by theobromine which also caused vertigo and nausea. Trichlorethylene prevented attacks, none occurring after third day of taking drug. The pain recurred whenever the drug was discontinued. Blood pressure after trichlorethylene 130 systolic and 90 diastolic. Under observation one year. Died of pneumonia.

Case 8 White male, aged 47. Hypertensive cardiovascular disease. Coronary thrombosis one month previously. Continued severe attacks of anginal type of pain while in bed. Blood pressure, 170 systolic and 120 diastolic. Electrocardiogram Leads I and II type coronary curve. Complete incapacity. No relief from theobromine. Complete prevention of pain by trichlorethylene, the pain recurring when drug discontinued. Patient under observation three years and in the last 12 months has resumed his occupation, which requires much walking. Blood pressure after taking trichlorethylene, 140 systolic and 100 diastolic, and has remained at about this level. At the present time the patient has an occasional sensation of oppression behind the sternum and a single inhalation of trichlorethylene will promptly relieve this.

Case 9 White male, aged 60. Hypertensive arteriosclerotic cardiovascular disease. Two weeks previously there had been an attack diagnosed as acute coronary thrombosis. Continued attacks of severe precordial pain at times radiated to left arm, occurring while in bed. Blood pressure before attack, 190 systolic, immediately after, 130, for week preceding examination by me, 170, at time of examination, 200 systolic and 100 diastolic. Electrocardiogram none. Trichlorethylene completely prevented the pain, pain returned when drug was discontinued. This patient later took inhalations for the immediate relief of anginal attacks with success. Blood pressure from 185 systolic and 100 diastolic to 200 systolic and 110 diastolic. Patient living two years later, occasional pain, no regular medication.

Case 10 White male, aged 61. Hypertensive arteriosclerotic cardiovascular disease of two years' known duration. Angina pectoris of one year's duration. Eight months ago diagnosed coronary thrombosis. At time of examination doing office work several hours daily, very slight exertion caused constricting pain behind sternum radiating to both arms. Blood pressure, 260 systolic and 130 diastolic. Electrocardiogram Left axis deviation, T_1 and T_2 inversion. During the first two weeks of taking trichlorethylene there occurred only one attack of mild pain. Patient was walking eight blocks without difficulty. Blood pressure, 200 systolic and 110 diastolic. Two months later at full work, but occasional heavy sensation over precordium. Trichlorethylene discontinued. At present patient takes occasional

courses of theocalcin. Trichlorethylene in single inhalations failed to influence immediate seizures. There is now a severe arteriosclerotic retinitis with visual impairment.

Case 11 White male, aged 64. Diabetes mellitus, arteriosclerotic cardiovascular disease, angina pectoris. Blood pressure, 160 systolic and 110 diastolic. Electrocardiogram T_1 and T_2 inversion, arched ST segments. Pain occurs on walking a little rapidly, or on going up moderate hills, at times after meals. The blood pressure remained about the same after taking trichlorethylene. There was greatly increased but not complete freedom from pain while taking this drug, and the pain would recur several days after the drug was discontinued. This patient was followed four months.

Case 12 White male, aged 53. Diabetes mellitus, arteriosclerotic cardiovascular disease. Anginal pain occurring if patient walked four blocks. Blood pressure, 140 systolic and 100 diastolic and remained at this figure after trichlorethylene was used. There was complete prevention of pain. This patient was treated with trichlorethylene for only one month because of expense of treatment. Pain recurred after trichlorethylene was discontinued. Electrocardiogram normal.

Case 13 White male, aged 56. Diabetes mellitus, arteriosclerotic cardiovascular disease. Anginal pain produced by moderate exertion. Blood pressure, 150 systolic and 100 diastolic and not affected by trichlorethylene, which also did not affect the pain during three weeks treatment. Electrocardiogram left axis deviation.

Case 14 White male, aged 43. Hypertensive cardiovascular disease, neurotic type personality. Anginal type of pain, moderate exertion causing pain. Electrocardiogram left axis deviation, slurring of QRS waves. Blood pressure, 160 systolic and 120 diastolic. Blood pressure after trichlorethylene, 135 systolic and 95 diastolic. Theobromine derivatives gave this patient no relief. There was complete absence of pain while taking trichlorethylene, and the pain recurred when the drug was discontinued and the blood pressure returned to 150 systolic and 110 diastolic.

Case 15 White male, aged 38. Coronary thrombosis two years previously. Blood pressure 120 systolic and 80 diastolic. Electrocardiogram at time of occlusion acute coronary curve, Lead II and Lead III type. Curve, two years later, large Q_2 and Q_3 , slurring of QRS and T_2 inversion. This patient had a heavy feeling of pressure behind the sternum on walking as little as a block or on going up one flight of stairs. This feeling completely disappeared while taking trichlorethylene three times daily, and the patient resumed his occupation at the end of three weeks. On reducing the trichlorethylene to once daily the pain returned but not as frequently as formerly. On again taking the drug three times daily there was no pain. He has changed his occupation to one of considerable mental strain, and short periods of great activity, discomfort does not occur as long as trichlorethylene is taken.

Case 16 White male, aged 59. Hypertensive arteriosclerotic cardiovascular disease. Anginal pain on moderate exertion, able to carry on occupation as insurance adjuster without great difficulty. Blood pressure, 178 systolic and 120 diastolic. Electrocardiogram Lead II and Lead III type coronary curve. No relief from immediate attacks on exhibition of trichlorethylene and attacks not lessened in frequency and severity in two weeks' trial. He refused to take this drug longer. The blood pressure was not affected. The patient obtained moderate relief with theocalcin. Patient died 20 months later, from coronary thrombosis.

Case 17 White male, aged 40. Gives history of hypertension, but this was not found at examination. Anginal type of pain, of moderate severity, not incapacitating. Blood pressure, 140 systolic and 100 diastolic. Electrocardiogram Left axis deviation. Complete prevention of pain with trichlorethylene. Neurotic personality. No history available after one month.

Case 18 White male, aged 55. Arteriosclerotic cardiovascular disease. One

year previously this patient had had an attack of severe precordial pain radiating out the left arm and lasting 48 hours. He was kept in bed for six weeks. During this time an electrocardiogram revealed low voltage, slurring of QRS waves, T_2 and T_1 inversion. An electrocardiogram six months later showed only T_1 inversion and low voltage. There had been several minor attacks preceding the severe one. Following the major attack the patient had frequent attacks daily occurring with anger, excitement or exertion, and more severe in cold weather. At time of examination the blood pressure was 120 systolic and 80 diastolic. Electrocardiogram Low voltage, otherwise normal mechanism. Complete relief in 24 hours after starting inhalations of trichlorethylene. There was no effect upon blood pressure. Patient under observation for six months at time of writing only occasional attacks of mild pain. This patient was very high-strung and irritable and he has noted a marked diminution in this irritability since taking trichlorethylene. It has been inhaled three times daily throughout the period of observation.

Case 19 Colored male, aged 41. Syphilitic aortitis, aortic insufficiency, angina pectoris. Blood pressure, 140 systolic and 60 diastolic. Trichlorethylene lessened the severity and frequency of pain to a moderate degree during a month's treatment. The patient was receiving antiluetic treatment. Electrocardiogram Left axis deviation.

Case 20 White male, aged 56. Arteriosclerotic cardiovascular disease. Coronary thrombosis five months before examination. Total disability because of recurring anginal pain on slight exertion or excitement. Blood pressure, 220 systolic and 140 diastolic. Immediate attacks at first had been relieved by amyl nitrite, which caused severe headache. Trichlorethylene prevented attacks for two months and then lost this effect, but it continued to afford relief in immediate attacks of pain. Electrocardiogram Lead II and Lead III type of coronary curve.

Case 21 White male, aged 54. Arteriosclerotic cardiovascular disease. History of coronary thrombosis two years previously, since that time retrosternal oppression on exertion or excitement. Blood pressure, 150 systolic and 90 diastolic. Lead I and chest lead type of coronary curve. Theobromine gave no relief. Trichlorethylene prevented such pain for a period of one month. No observations since this time. No effect upon blood pressure.

Case 22 White male, aged 76. Arteriosclerotic cardiovascular disease. Electrocardiogram Left axis deviation, slurring of QRS. Infected gangrene of right foot. Paroxysmal pains of anginal type occurring while in bed and persisting after amputation. Relieved by amyl nitrite. Blood pressure, 150 systolic and 100 diastolic. Frequency and severity of pain markedly diminished while taking trichlorethylene both before and after amputation. No change in blood pressure.

Case 23 White male, aged 68. Arteriosclerotic cardiovascular disease, angina pectoris. Crushing precordial pain caused by exertion or excitement, relieved by nitroglycerine. Nitroglycerine caused severe headache. Blood pressure, 150 systolic and 105 diastolic. Two weeks after trichlorethylene, blood pressure 130 systolic and 80 diastolic, no pain since drug started. Six months later at work, occasional pain much less severe than formerly. Continues to take trichlorethylene daily. Electrocardiogram left axis deviation (see footnote on page 1192).

Case 24 White male, aged 48. Hypertensive arteriosclerotic cardiovascular disease, angina pectoris. Squeezing vice-like, retrosternal pain radiating out left arm, occurring only on exertion. Known hypertensive for several years. Blood pressure, 190 systolic and 130 diastolic. Pain occurred on walking rapidly for two blocks. Electrocardiogram slurring of QRS waves, convex ST_2 , inverted T_1 . Blood pressure two weeks after trichlorethylene, 175 systolic and 105 diastolic. Estimated 20 per cent improvement. Six weeks after trichlorethylene, blood pressure 130 systolic and 85 diastolic, could walk 10 blocks rapidly. Four months later could

walk 20 blocks without pain, blood pressure, 128 systolic and 80 diastolic. Trichlorethylene discontinued. Returned in three weeks with blood pressure 140 systolic and 100 diastolic and occasional return of pain. Again the pain was prevented by trichlorethylene inhaled three times daily and patient continues to take this drug, varying the frequency of inhalation from one to three times daily according to the return of pain.

Case 25 White male, aged 76. Arteriosclerotic hypertensive cardiovascular disease, angina pectoris. Heavy oppression in chest on slight exertion such as walking one-half block up slight grade. Relieved by amyl nitrite, but this drug caused headache. Trichlorethylene failed to relieve immediate attacks of pain. Blood pressure, 170 systolic and 105 diastolic. Electrocardiogram. Left axis deviation, slurring of QRS waves. Trichlorethylene used for two weeks, discontinued because it produced unconsciousness at times and this caused the patient great anxiety. There had been no effect upon the pain. Blood pressure at the time of the drug's discontinuance 180 systolic and 110 diastolic.

Case 26 White male, aged 57. Chronic nephritis, tumor of urinary bladder, generalized arteriosclerosis, angina pectoris, uremia. Anginal pain of one year's duration. At time of initiation of treatment pain was caused by the slightest exertion such as getting out of bed. Trichlorethylene one ampoule by inhalation thrice daily. In one week he was able to be up and move about ward. At this time exercise tolerance over standard portable steps equaled two round trips. At end of second week he was able to make seven or eight round trips. Electrocardiogram. Left axis deviation. Patient died, uremic coma, at end of third week. Anatomical diagnosis: chronic cystitis, bilateral chronic nephritis, generalized arteriosclerosis, coronary sclerosis, fibrosis of apex of right ventricle, fulguration necrosis of bladder wall.

Case 27 White male, aged 50. Arteriosclerotic cardiovascular disease, angina pectoris. One year previously this patient had suffered from a coronary occlusion. The electrocardiogram at that time was of the Lead I, chest lead type of acute coronary occlusion curve. Following the above illness the patient never was able to return to his occupation of executive because of recurring seizures of angina pectoris. Five weeks before death the patient became bedridden, precordial pain occurring in severe seizures while at rest. Theobromine derivatives were of help in diminishing the frequency and severity of attacks. The patient was given inhalations of trichlorethylene three times daily and inhalations for immediate attacks over a period of three weeks without appreciable benefit. Nitroglycerine failed to relieve the pain. He died in a prolonged attack of pain during which the electrocardiogram revealed a Lead III type of acute coronary curve.

I can offer no adequate explanation of why this drug is effective in preventing attacks of angina pectoris. The fall in blood pressure at times noted may be a factor in some cases, but obviously cannot explain the greater number of cases in which no such reaction has taken place. No constant effect upon coronary circulation has been shown to occur. There is no evidence that conduction of nerve impulses is impaired. There is definite evidence that this drug has sedative and anesthetic properties. A few unrelated observations have been made upon pain due to other causes, and in the cases so treated a sedative and hypalgesic action has been noted. In the case histories it is frequently stated that the patients are of high-strung, nervous temperament. The hypalgesic and sedative action of this drug is the only explanation of its effectiveness in preventing and relieving angina pectoris with any evidence in its favor at this time.

SUMMARY AND CONCLUSIONS

1 The inhalation from two to four times daily of ampoules of trichlorethylene, containing 1 c c, has been used with some success in the prevention of attacks of angina pectoris. However, this series is not sufficiently large to warrant too favorable conclusions, since in any small series there may be a considerable distortion due to the element of chance.

2 While pure trichlorethylene in the recommended dosage does not seem to be toxic, nevertheless, because of the reported cases of industrial poisoning due to this agent, it should be used with some caution.

CASE REPORTS

TREATMENT OF HEMOLYTIC STREPTOCOCCIC MENINGITIS WITH PARA-AMINO-BENZENE-SULFONAMIDE, REPORT OF A CASE, WITH RECOVERY

By JAMES G. ARNOLD, JR. M.D., *Baltimore, Maryland*

THE observations of European investigators and more recently of Long^{1,2} and Schwentker³ in this country on the treatment of beta hemolytic streptococcal infections by para-amino-benzene-sulfonamide suggested to the author the use of this drug in infections of the central nervous system. The opportunity presented itself to try this drug on a case of fulminating meningitis following a middle ear and mastoid infection admitted to the Neurosurgical Service of Dr. Charles Bagley, Jr., at the University of Maryland Hospital on December 18, 1936. The dosage used in the treatment of this case was the same as that used by Schwentker³ in a similar case treated by him several weeks previously. It seems worthwhile to make this preliminary report of a single case because of the striking therapeutic results. The rapid recovery of a patient suffering from a disease which is practically always fatal strongly suggests that the treatment employed may have had a specific effect.

CASE REPORT

History On December 5, 1936, the patient, a white female 28 years of age, began to have earache in the right ear. Later that evening the ear began to discharge followed by some relief from pain, but the pain continued somewhat until about December 12. From December 12 to December 17 she seemed much improved. On December 16 she went to bed feeling quite well, but was awakened at 3:00 a.m. with severe headache. By morning she had become very confused and drowsy. Her father stated he was "unable to get anything out of her." Her family physician took her to the Frederick City Hospital on December 17 where she was seen by Dr. A. A. Pearre. There a diagnosis of meningitis was made clinically and examination of the cerebrospinal fluid on December 17 showed 3880 cells with 79 per cent polymorphonuclears. No bacteria were seen in the smear. Examination of the blood revealed a white cell count of 29,600. The following morning she was admitted to the Neurosurgical Service of Dr. Charles Bagley, Jr., at the University Hospital. While the patient was being transferred from Frederick to Baltimore, Dr. Pearre called and stated that the spinal fluid culture taken the day before was positive for *Streptococcus hemolyticus*. The past history was negative.

Examination On admission the patient appeared critically ill. The skin was flushed and hot. She was unresponsive and reacted only to painful stimuli. There was a yellowish watery discharge from the right ear. No swelling over mastoid or ear. Divergent strabismus. Deep reflexes equal and hyperactive. Kernig positive.

* Presented before the Neuropsychiatric Section of the Baltimore City Medical Society, January 14, 1937.

From the Department of Neurosurgery, University of Maryland Medical School, Baltimore, Maryland

Abdominals diminished Bilateral plantar extensor response Rigidity of neck with mild opisthotonos Hearing reduced in left ear (since childhood) Peripheral facial paralysis on right side

On December 22, 1936, the examination of the blood was as follows Hemoglobin 100 per cent, r b c 4,400,000, w b c 5600, polymorphonuclears 89 per cent, lymphocytes 10 per cent, large mononuclears 1 per cent Blood non-protein nitrogen 27 mg per cent, blood sugar 114 mg per cent Wassermann reaction negative On December 26 the white blood cells were 20,000, polymorphonuclears 88 per cent, lymphocytes 10 per cent, large mononuclears 2 per cent Sedimentation rate 34 mm in one hour On January 5, 1937 the white blood count was 11,000 The blood culture of December 18, 1936, was negative after five days A smear of the pus taken from the ear on December 19 revealed pus cells polymorphonuclears predominating, together with gram-positive diplococci and streptococci A culture of this pus showed *Staphylococcus aureus* Urine examinations were entirely negative on December 26, January 1, and January 6 The findings in the spinal fluid are cited below

Course On admission to the hospital the patient was very stuporous The temperature was 105.4° F (R) A mastoid infection was considered likely because of the peripheral facial paralysis but it seemed useless to consider operation Examination of the spinal fluid in the Frederick City Hospital on December 17, 1936, had shown a pleocytosis of 3880 cells per cu mm and a positive culture for hemolytic streptococci Immediately upon admission late in the afternoon of December 18, the spinal fluid was found to be cloudy, contained 5181 cells, and was under a pressure of 333 mm of water The next morning the culture from this fluid showed a heavy growth of beta hemolytic streptococci In the afternoon of December 19, a second puncture was done and the fluid was found to be under a pressure of 440 mm of water Twenty-five cubic centimeters of fluid were withdrawn and 20 c c of 0.8 per cent para-amino-benzene-sulfonamide in normal saline solution were injected intraspinally Following this a subcutaneous injection of 200 c c of the same drug was given Treatment was continued from this point on as described in a later section and summarized in table 1

On December 20, twenty-four hours following the administration of the drug, the temperature dropped to 104° F and there was a striking decrease in the spinal fluid cell count from 5181 to 1026 The pressure also dropped from 440 to 240 mm of water The patient was able to take fluids by mouth, smiled occasionally, but was still drowsy and disoriented Once or twice she inquired about her surroundings, but late in the evening she again became very unresponsive

On December 21, the temperature dropped to 102° F (R) and the patient seemed slightly improved In the afternoon she became more confused and resistive She muttered to herself frequently The spinal fluid pressure was 110 mm of water, contained 1134 cells, and the culture was still positive for *Streptococcus hemolyticus*

On December 22 she refused food She became moderately cyanotic and the respiratory rate increased to 40 She was very noisy and cried out frequently The spinal fluid pressure was 90 and the cell count dropped to 600 In previous cultures the organisms grew out overnight, but the culture taken on this day showed a very sparse growth in 36 hours

On December 23, she was more cooperative but was still mildly disoriented The temperature dropped to 99.4° F (R) A bloody tap was obtained on doing the spinal puncture A smear was made from the fluid and showed a few gram-positive cocci, but the culture was sterile A transfusion of 300 c c of blood was given without reaction The respiratory rate continued around 40 At no time during her course had there been swelling over the mastoid process, but in view of the general improvement, it was felt wise to consider doing a mastoidectomy Roentgen-ray of the mastoids was done and Dr H J Walton reported "moderate clouding of

TABLE I
Chart Showing Cerebrospinal Fluid Findings and Record of Treatment

Day of disease	3	4	5	6	7	8	9	10	11	12	13	14	15	16	18	19	20	22	28

Chart of the temperature, pulse and respiration during the course of hemolytic streptococcic meningitis

the cells in the right mastoid process, suggestive of an infection. There is no indication of breaking down of the cell partitions." His impression was "mastoiditis, probably acute."

On December 24, the temperature again rose to 102.4° F (R). In the afternoon Dr. E. A. Looper did a right semi-radical mastoidectomy. The mastoid was found to be necrotic and filled with pus. The mastoid cells were curetted and the antrum opened widely. The ossicles and drum were removed. The dura was exposed above and the lateral sinus below. The patient stood the procedure well. It is of great interest to note that the spinal fluid had become sterile on the previous day.

On the following morning, December 25, the temperature dropped to 99.6° F. Her condition was definitely improved. She was more alert and talked with visitors. In the afternoon a second transfusion of 300 cc was given. She had a reaction following this and the temperature rose to 104.6° F (R). The right ear and mastoid were draining profusely. The spinal fluid cell count was 450, pressure 300 (patient struggling), and culture of the spinal fluid was negative. Slight cyanosis of the skin was still present.

On December 26, her color was improved and respirations were slower. She was able to feed herself, talked coherently, and was definitely more alert mentally. She talked with her visitors and seemed cheerful. The temperature dropped to 98.4° F (M) and the cell count to 325.

From this time on her improvement was steady. Between December 26 and January 4, the temperature ranged between 98.4° F (M) and 100.6° F (M). The medication was discontinued on January 3, and on January 5 the temperature dropped to a normal level. Between January 5 and January 12 the temperature rose to 100° F (M) on two occasions. The cell count dropped to 40 on January 11. Ten consecutive cultures of the spinal fluid were sterile. Since January 8, she has been allowed out of bed.

Examination on January 11 showed her to be bright and mentally alert. Her father could see no change in her mental acuity. The peripheral facial paralysis on the right side noted on admission was still present. The deep reflexes were all hyperactive, with bilateral ankle clonus. The plantar responses were equivocal. The fundi were normal.

Treatment. Between December 19, 1936, and December 27 the patient received nine intraspinal injections of 0.8 per cent para-amino-benzene-sulfonamide in amounts ranging from 20 to 35 cc, depending upon the amount of fluid withdrawn. On December 19 and 20, respectively, 200 cc (1.6 gm) and 350 cc (2.8 gm) of 0.8 per cent para-amino-benzene-sulfonamide were injected subcutaneously.

On December 21, 22, and 23, 6 gm of the substance were given in the form of "Prontylin" tablets by mouth, 3 tablets six times a day. From December 24 to January 3 she was given 4 gm every 24 hours, or 3 tablets four times a day.

As yet the optimum dosage of this drug* in the treatment of beta hemolytic streptococcal infections is undetermined. Long feels that large doses should be given in the first few days of treatment. He has found that patients tolerate a dose of 1 gm per 20 lb of body weight every 24 hours for as long as a month. He has pointed out that the drug administered orally should be given in divided doses over a 24-hour period.

In this case, four intraspinal injections were given after the spinal fluid became

* The crystalline para-amino-benzene-sulfonamide used was made by the Du Pont Chemical Company, and the "Prontylin" tablets by the Winthrop Chemical Company. Two derivatives of para-amino-benzene-sulfonamide are on the market under the name of "Prontosil" solution and "Prontosil" tablets. Prontosil solution may be used for subcutaneous injections but not intraspinally, for Schwentker³ has found that Prontosil solution increases the cellular reaction in the leptomeninges and is therefore more irritating than solutions of para-amino-benzene-sulfonamide. For further discussion of these derivatives the reader is referred to Long's paper.¹

sterile, and the drug was continued by mouth for 11 days after obtaining a sterile spinal fluid

In the preparation of the powdered para-amino-benzene-sulfonamide for parenteral and intraspinal injection, sterile normal salt solution was brought to a boil and the powder slowly dropped in. Long has found that no further sterilization is necessary. The solution should be prepared just before using.

Comment As with any new drug, the therapeutic value of this new chemotherapeutic agent can be determined only after prolonged use. In this one case, however, it appears that para-amino-benzene-sulfonamide produced a powerful bacteriostatic effect in a fulminating case of beta hemolytic streptococcal meningitis. Twenty-four hours after the injection of 1.6 gm subcutaneously and 0.016 gm intraspinally the spinal fluid cell count dropped from 5181 to 1026. Throughout the course there was a steady decrease in the cell count and on the tenth day following treatment the cell count had dropped to 78 and on the twenty-second day to 40.

The cerebrospinal fluid pressure before treatment was 440 mm of water. Within 24 hours, the pressure dropped to 240 mm of water, and thereafter did not exceed 200 mm except on one occasion when the patient was straining during the puncture, when it was found to be 300.

Before treatment, the spinal fluid cultures were found to be positive for beta hemolytic streptococci, both in the Frederick City Hospital and at the University Hospital. For two days following the institution of treatment, cultures of the organism grew out promptly within 24 hours. On the third day following treatment, the growth became sparse and required 36 hours. On the fourth day a few gram-positive cocci were found in the smear, but the culture was sterile. Following this, 10 consecutive negative cultures were obtained. This behavior of the spinal fluid cultures is further evidence of the bacteriostatic power of the drug on beta hemolytic streptococci. This marked reduction in cell count corroborates Schwentker's finding³ that the drug itself produces no cellular response in the leptomeninges. Furthermore in this case, the inflammatory reaction of the leptomeninges was greatly decreased after one intraspinal injection.

Because of the existing peripheral facial paralysis at the time the patient was admitted to the hospital, it was felt that she had a mastoid infection and that the portal of entry was through the mastoid, even though there was no swelling in the region of the mastoid. Because of the heretofore hopeless outcome of streptococcal meningitis, it was thought best to see if the patient responded to the drug before subjecting her to a mastoidectomy. That the drainage of the mastoid bore no relation to the decrease in meningeal reaction is shown by the fact that the spinal fluid cultures became negative on December 23, twenty-four hours before the mastoidectomy was performed. This operation was considered worthwhile at this time only because of the striking improvement in the patient's general condition.

In the treatment of streptococcal meningitis with this drug, the exact required dosage is as yet undetermined. The dosage given this patient seemed to be adequate and until further data are forthcoming it is suggested that the intraspinal injection be continued until three consecutive negative cultures are obtained, and that the oral administration be continued for 10 days following the last positive spinal fluid culture. As pointed out by Long, unless the drug is given for a sufficient length of time there may be a relapse of the infection.

Whether or not parenteral and oral administration of the drug will control infection in the central nervous system without intraspinal injection has not yet been determined

The drug is relatively non-toxic but two complications, sulphemoglobinemia and acidosis, are occasionally encountered. Should either occur, the drug should be discontinued or the dosage decreased for 24 to 48 hours. Acidosis may be relieved by parenteral injection of 5 per cent sodium lactate.

I wish to express my appreciation to Dr. Perrin H. Long and Dr. Francis F. Schwentker for supplying me with the drug and for their suggestions in the treatment, to Dr. Charles Bagley, Jr., for permission to publish the case, and to Dr. N. Davidson for his assistance in treating the patient.

INTERMITTENT HYPERTHERMIA OF SEVEN YEARS' DURATION

By EDGAR V. ALLEN, M.D., F.A.C.P., *Rochester, Minnesota*

A MECHANICAL engineer, 38 years old, was admitted to the Clinic September 27, 1935, complaining of attacks of fever during a period of seven years. The patient was born in Dayton, Ohio, and moved to southern California at the age of eight years. He had never been in the tropics, in South or Central America or in Mexico other than in parts within 50 miles of the California border. He had had measles and whooping cough as a child, and while serving in the Navy in 1918 had had measles complicated by lobar pneumonia.

Between the ages of 23 and 35 he had had severe frontal headaches associated with photophobia, but without nausea and vomiting. In 1926 repeated washing of both antrums relieved the headaches markedly but not completely. In 1928, at the age of 31, he had an attack of influenza characterized by malaise, fever and weakness. There was no associated somnolence or insomnia. About six weeks later he experienced the first of the attacks of fever, which attacks had occurred intermittently ever since.

The attacks of fever varied greatly in intensity (figure 1). They were preceded by prodromal symptoms by as much as 24 to 48 hours, such symptoms consisting of aching in the neck, shoulders, small of the back and feet and ankles, and often in the hands and wrists. Chilliness, and often severe chills, were experienced. Occasionally nausea and vomiting occurred as the temperature of the body increased. When the temperature reached the maximum, the patient perspired profusely and his temperature then began to decrease. Usually he slept during the time his temperature was returning to normal. He would lose from four to seven pounds (1.8 to 3.2 kg.) during such attacks.

* Read before the meeting of the Minnesota Society of Internal Medicine, Duluth, Minnesota, June 6, 1936.

From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

Twenty-four hours after an attack the patient felt entirely well. In later years, severe chills and nausea which had formerly almost invariably accompanied episodes of fever had become very rare, and aching of the legs, which had occurred as a prodromal symptom in the earlier years, had been replaced by aching of the feet and ankles. Aching in the neck, shoulders and small of the back had occurred with the attacks only in the past three or four years. The attacks had gradually increased in

FIG 1 The inconstancy of the response shown by charting the temperature of the body during three (A, B and C) spontaneous attacks of fever

number from about 10 in 1929 to 46 in 1935. The average of numerous determinations of body temperature between episodes of fever was roughly 97.6° F. The longest interval in which no attack had occurred had been 100 days, in 1933. Complete records had been kept in 1934 and 1935, and during this time the longest interval between attacks was 15 days and the shortest, six days. The mild and severe attacks occurred with no regularity, there being no relationship between the intensity of attacks and the interval between them (figure 2).

During the six years prior to examination at the Clinic the patient had been under the supervision of a number of physicians, but their examinations had always given essentially negative results. Agglutination tests for undulant fever, examination of the blood for malarial organisms and spirochetes, urinalyses, and various roentgenologic examinations, had always been negative. Neoarsphenamine (given

FIG 2 The upper part of the chart indicates the intervals between attacks during 1935 and 1936, the shortest interval between episodes of fever was six days, the longest 15 days. The temperatures attained during attacks, which varied from 98.8° to 104.4° F, are shown in the lower part of the chart.

intravenously four times at weekly intervals), oxyquinoline sulphate (given in retention enemas and by mouth for several months) and quinine sulphate (in amounts of 20 grams [13 gm.] during the prodromal stages of three attacks), had been without benefit. Two brands of acetylsalicylic acid (empirin and aspirin) have been found to lower the body temperature substantially, although the fever persisted over a longer period when these drugs were taken.

Physical examination at the Clinic revealed small tonsils and evidence of sinus infection. No evidence of any abnormality was found on examination of the heart, lungs, abdomen, lymph nodes, and extremities, or prostate gland, seminal vesicles, and epididymides. A complete neurologic examination also gave negative results. Proctoscopic examination showed nothing significant. Examination of the eyes was negative except for evidence of old choroiditis on the nasal side of the right macula and a small opacity near the periphery of the lower nasal quadrant of the right lens. The blood pressure in millimeters of mercury was 100 systolic and 70 diastolic. Routine examination of the urine and blood, including determination of the values for hemoglobin and blood urea, enumeration of erythrocytes, examination of blood smears, and a serologic test for syphilis, were all negative. Leukocytes numbered 8,300 per cubic millimeter of blood, of which 46 per cent were lymphocytes, 6 per cent monocytes, 46 per cent neutrophils and 2 per cent eosinophils. Bronchoscopic examination failed to reveal any evidence of bronchiectasis. Visualization of the kidneys following the intravenous injection of neo-iodopax showed them to be entirely normal. Agglutination tests of the blood for *Pasturella tularensis* and *Brucella abortus* were negative. A tuberculin test was positive. Roentgenologic examination of the sinuses disclosed markedly thickened membrane in the right antrum, and that of the teeth some evidence of infection in one tooth. There was no growth of organisms on culture of the urine. Cultures from the nasopharynx revealed streptococci,

and those of prostatic secretion both streptococci and staphylococci. The sedimentation rate of erythrocytes was 5 mm in one hour.

The patient was then observed in the hospital during an attack of fever. His temperature rose from 97.2° to 100.4° F in eight and a half hours, and then decreased to 97.6° F in three and a half hours. The pulse rate increased to 120 beats per minute. Urine, passed when the temperature was 101° F, was normal. Examination of blood smears for malarial organisms, spirochetes and trypanosomes was likewise negative at this time. Leukocytes numbered 20,000 per cubic millimeter, 28 per cent being lymphocytes, 3 per cent monocytes, 67 per cent neutrophils, 1 per cent eosinophils and 1 per cent basophils, there was evidence of moderate toxicity of the leukocytes. The sedimentation rate was 7 mm in one hour. Spinal puncture, made when the temperature was 101.0° F, showed normal pressure responses, analysis of the spinal fluid gave negative Wassermann, Kline and Nonne reactions and revealed 3 small lymphocytes per cubic millimeter, the total protein being 30 mg and the colloidal gold curve 0 111 100 000. Blood cultures on brain broth and on blood agar were negative.

On October 2 the infected tooth was removed, cultures from the root revealing streptococci. Because washings from the right antrum were purulent and contained streptococci and because the left antrum appeared to be involved in a similar manner, bilateral antral windows were made on October 8, 1935. On November 27 and 28 roentgen treatment* was given to the right and left sides of the head respectively. On November 2, subcutaneous injections of a vaccine made from organisms cultured from the nasopharynx were begun, injections being given twice weekly for five weeks in increasing doses, and subsequently in constant doses every week. None of these procedures influenced the recurrence of attacks in any way.

The patient was observed during several spontaneous attacks of fever. Possibility of malingering was excluded by constant observation and by use of an automatic rectal thermometer. During an episode of spontaneous fever 1/6 grain (0.01 gm) of pilocarpine was administered hypodermically, profuse salivation and sweating followed but the fever was not influenced in the ensuing hour. Three grains (0.20 gm) of sodium amytal administered by mouth then induced sound sleep although the fever was unaffected (figure 3A). At another time phenobarbital given in sufficient amount to cause somnolence did not prevent or modify an attack. During a subsequent attack ergotamine tartrate was given subcutaneously in amounts of 0.25, 0.25, 0.25, 0.25 and 0.50 mg, respectively, at hourly intervals, the course of the fever was unchanged (figure 3B). The temperature response to intravenously injected typhoid vaccine (figure 3C) was about the same as that observed during spontaneous episodes of fever (figure 3D). The response of body temperature to increased environmental temperature in a Simpson-Kettering fever cabinet and in a full-length body baker was considered normal (figures 3E and F). During a spontaneous attack, when the oral temperature was 102.0° F, 1/4 grain (0.016 gm) of morphine sulphate was given subcutaneously. The temperature increased another degree in the next hour, and remained at this height for two hours when spontaneous sweating set in and the temperature dropped (figure 3G). Although the patient slept during this period, no influence on the course of the fever was noted. In another attack amidopyrine was administered three times, in amounts of 10 grains (0.65 gm) at hourly intervals. The first dose induced some sweating and momentarily suspended the rise of the fever, after the second dose moderate sweating continued and the fever dropped, but not until nine hours later did it reach the individual normal of 97.6° F (figure 3H). During another spontaneous attack 15 grains (1.0 gm) of "Iarodon" (Hoffman-La Roche, Inc) was given by mouth when the oral temperature reached 100.0° F, an equal amount was given an hour later. The temperature only slightly exceeded

* 135 kilovolts, 16 inches, 5 milliamperes, 6 mm aluminum filter, 20 minutes

100° F and returned nearly to normal in seven hours, the fever recurred, however, eight hours later, and 15 grains of larodon was again given. Some effect on the temperature was again noted, but it did not become normal until 13 hours after the last (29 hours after the first) administration of larodon (figure 3I). These results

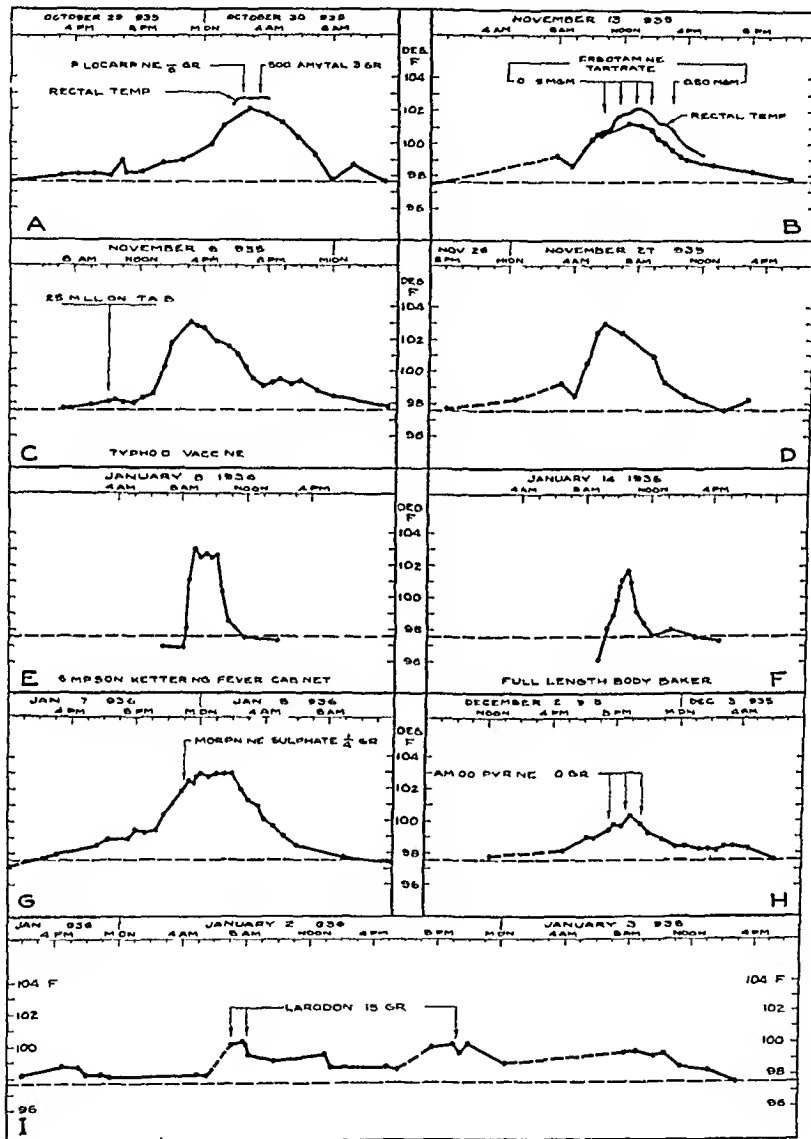

FIG 3 A, B and G illustrating the absence of effect of pilocarpine, sodium amytal ergotamine tartrate and morphine sulphate on the fever, H and I, the effects of amidopyrine and larodon in decreasing the fever, C, fever induced by injecting typhoid vaccine intravenously, which simulated closely that occurring spontaneously D, E and F, the response of the body temperature to increased environmental temperature, which was considered normal

were similar to those sometimes noted by the patient on using acetylsalicylic acid (empirin and aspirin) prior to coming to the Clinic

Typhoid vaccine was injected intravenously November 16, 18 and 30, and December 2 and 4 in amounts of 25, 40, 60, 85, and 120 millions of killed organisms,

respectively. On each occasion the oral temperature was elevated to between 102.7° and 103.3° F. The reactions, including symptoms and fever, were identical to those noted during spontaneous attacks of the same degree of fever. Spontaneous attacks of fever were experienced on November 27 and December 12. The first occurred on the ninth day after an injection of typhoid vaccine and on the fourteenth day after the preceding spontaneous attack, the second spontaneous attack occurred on the eighth day after an injection of typhoid vaccine and on the sixteenth day after the preceding spontaneous attack. Spontaneous attacks then occurred December 18 and 24, and on January 2, or at intervals of approximately six days. These results suggested that the fever induced by the intravenous injection of typhoid vaccine served as a substitute for the spontaneous attack, inasmuch as an interval of 14 or 15 days between spontaneous attacks had occurred only once in the last two years.

In the hope that fever induced artificially by any means would substitute for spontaneous attacks, on the sixth day after a spontaneous attack the body temperature was elevated to 103.0° F by mouth (103.4° F by rectum) and was kept at or near this level for an hour in a Simpson-Kettering fever cabinet. One day after this fever treatment, or seven days after the spontaneous attack, moderate spontaneous prodromes appeared and persisted for about two days, but no fever was observed. Five days after this fever treatment, or 12 days after the preceding spontaneous attack, the temperature was raised to 101.7° F (by mouth) in an ordinary full-length baker and was kept there for a few minutes. A spontaneous attack occurred four days later, or 15 days after the preceding spontaneous attack and nine days after the fever artificially induced in the fever cabinet. This suggested that the higher temperature maintained for an hour in the fever cabinet served as a substitute for a spontaneous attack and showed definitely that the lower temperature attained in the body baker for a short period did not so substitute. It should be noted that the total "fever area" in the first instance was over twice as great as in the second.

During another attack of fever, three injections of 9 minims (0.5 c.c.) each, of epinephrine were given at hourly intervals without effect on the fever. Another episode of fever occurred while the patient was taking phenobarbital, which made him very drowsy, 1 c.c. of pituitrin injected subcutaneously and 20 c.c. of whole blood injected intramuscularly did not influence the fever.

On February 3, 1936, Dr. E. C. Rosenow began a study of the patient from a bacteriologic standpoint. Blood agar platings of material from the nasopharynx and of pus expressed from the tonsils revealed unusually large numbers of green-producing streptococci. The cataphoretic velocity of these streptococci was normal. Skin tests made with the euglobulin fraction of the blood serum of horses, injected for immunization purposes with neurotropic and arthrotropic types of organisms, revealed a marked reaction in each instance, apparently indicating antigen of these organisms in the skin. Administration to the patient of the serum of horses so treated, on three successive days, greatly diminished this skin reaction, indicating, apparently, almost complete neutralization of the antigen in the patient's skin, although an attack of fever occurred at the expected time.

At this time the leukocytes numbered 7,400 per cubic millimeter of blood, 84 per cent of them being neutrophils, 7 per cent monocytes and 9 per cent lymphocytes. The sedimentation rate was 7 mm. in one hour. On February 9 serum sickness began, this was characterized by a temperature as high as 103° F, and by urticaria, chilly sensations, drowsiness and somnolence and generalized aching and erythema. The hands and feet were hot and swollen, the hands felt "asleep" at times, and there was slight aching of the eyes and head. The symptoms mentioned were moderately acute for three days and recovery was not complete for about a week after the symptoms began.

Tonsillectomy was performed February 13. Culture of the tonsils revealed the

same type of organism shown previously to be present in the nasopharynx and secretion from the tonsils. Two days after tonsillectomy another attack of moderate fever was experienced and, the following day, the fever was associated with acute bronchitis, this, however, disappeared rapidly.

The patient left our supervision on February 19, in order to return to his home, and his subsequent condition was reported by letter. He remained well. His physical and mental energy increased, he slept better, and in general his health was substantially improved over that of the preceding few years. Episodes of fever did not occur. In May, however, he wrote that intermittent nasal discharge, photophobia, and headache indicated sinus infection. His diagnosis seemed well founded, for on June 30 (136 days after the last episode and 137 days after tonsillectomy) a severe febrile episode occurred. This could hardly be a spontaneous remission since the longest interval between attacks in seven years had been 100 days and the longest interval in the preceding two years had been 15 days. After recovery from the attack just mentioned a physician confirmed the diagnosis of frontal sinusitis and non-surgical treatment was begun. Attacks of fever occurred at intervals of 68, 25, 14, 25 and 13 days.*

COMMENT

It was apparent from the history of this patient's illness that an etiologic basis for the recurrent attacks of fever would be difficult if not impossible to establish. This assumption was strengthened by the paucity of findings from examinations elsewhere and from routine examinations at the Clinic. The patient, however, was cooperative and was desirous of obtaining a cure for his condition, regardless of the length of time required or the inconveniences which such an intensive investigation would entail. The possibility that the patient was malingering was eliminated promptly by observing him during episodes of fever and by personally determining his oral and rectal temperature. The elevation of the pulse rate was further evidence that the fever was real.

The first diseases to be considered were malaria, bronchiectasis, pyelitis or pyelonephritis, bacilluria, Hodgkin's disease, undulant fever, filariasis, trypanosomiasis, spirochetosis, tularemia and the blood dyscrasias. No evidence of any of them was found. A transcription of the patient's record was subsequently sent to Colonel Charles F. Craig, Director of the Department of Tropical Medicine at Tulane University, in the faint hope that the patient might have some unusual tropical disease with which we were unfamiliar. Colonel Craig kindly reviewed the record and replied that he was quite certain that the condition was not one of tropical infection.

The next step was elimination of obvious foci of infection, although there was little hope that such a procedure would influence the attacks of fever. When the surgical treatment of infected antrums and extraction of an infected tooth were unavailing, it was apparent that the situation was a difficult one and that investigation along the lines reviewed and discussed by Dr. H. A. Reimann, of the University of Minnesota School of Medicine, should be carried out. The possibility of a psychogenic fever was promptly eliminated by failure of morphine and amytal to influence the fever reactions. Further, an attempt was made to influence the fever by roentgen irradiation of the head, after considering the possibility that the fever was of central origin and was caused by a disturbed heat-regulating center. No results were obtained by these measures and in desperation an attempt was then made to eliminate the spontaneous at-

* At this time (January 15, 1937) the patient is experiencing episodes of fever of about the same type as before tonsillectomy was performed.

tacks of fever by inducing it artificially. While the results of this procedure were valueless from a preventive standpoint, there was considerable but not conclusive evidence that artificially induced fever substituted for the spontaneous attacks. Finally, further consideration was given to the possibility that the fever was of infectious origin. Reimann has reviewed evidence that fever of infectious origin responds to antipyretic drugs, while normal temperatures and psychogenic fevers do not. Our studies indicated that the antipyretics, amidopyrine and "larodon," definitely influenced the fever, whereas pilocarpine, ergotamine tartrate, morphine, amytal and epinephrine did not. These results suggested that the fever was produced by infection. This was further suggested by an increase in the number of leukocytes per cubic millimeter of blood and an increase in the percentage of neutrophils on one occasion, and by an increase in the percentage of neutrophils without an increase in the number of leukocytes during fever on another. Dr. Reimann then reviewed our study records and reported that he believed the fever was quite definitely of infectious origin, probably from some focus of infection.

It is interesting that there was no significant increase in the sedimentation rate. However, Reimann has pointed out that failure of the speed of sedimentation to increase during fever does not exclude an infectious origin. Because of the possibility of some hidden focus of infection, Rosenow's hyperimmune streptococcus antiserum was given, but an attack of spontaneous fever occurred at the expected time. Serum sickness followed the administration of horse serum, and before a sufficient interval had elapsed to determine whether or not another episode of fever would follow, tonsillectomy was performed because the tonsils were the only remaining possible focus of infection. Much to our surprise attacks of fever did not occur subsequently while the patient was under our observation, and he has reported that none occurred for four and a half months after his dismissal from the Clinic. He reported further that his general health had improved greatly. The evidence is quite clear, therefore, that either serum sickness or tonsillectomy produced the good therapeutic results. The former assumption appears quite untenable, and there can be no reasonable doubt but that the organisms in the tonsils were responsible for the recurrent attacks of fever. A return of episodes of hyperthermia after the longest free interval in seven years was definitely associated with frontal sinusitis. It seems fairly certain, therefore, that the episodes of hyperthermia were of infectious origin and that the organisms responsible for them lodged in the tonsils and sinuses.

SUMMARY

Study of a patient who had recurrent episodes of hyperthermia for seven years indicated that his fever was of infectious origin. Tonsillectomy produced temporary cessation of these attacks of fever when all other methods of treatment which were tried had been without avail. Recurrence of attacks was associated with frontal sinusitis.

PRIMARY CARCINOMA OF THE LIVER WITH BONE METASTASIS

By HERMAN BOLKER, M D , MENDEL JACOBI, M D , and MORRIS T
KOVEN, M D , *Brooklyn, New York*

PROVED cases of primary carcinoma of the liver are few in number, particularly so in comparison with the frequent occurrence of secondary neoplasms of that organ, which are found in about 25 per cent of autopsies. Distant metastases of new-growths primary in the liver are potentially common because of the characteristic tendency of the cells to invade the walls and lumina of the venous radicals. Of these metastases, one of the most unusual is that to the skeletal system, a search of the literature revealing only the following nine instances.

Schmidt,¹ in a man of 55, found a primary tumor in the right lobe of a cirrhotic liver, which had invaded the portal veins, and metastasized to the retro-peritoneal tissues, lungs, bronchial glands, skull, sternum and sacrum. Bile capillaries containing yellow staining pigment were noted among the neoplastic cells in the metastases.

Huguennin's² case occurred in a man of 50 years who was known to have had a nodular liver for five years before death. At autopsy, the liver was cirrhotic and contained numerous reddish and green tumors, the former type showing venous invasion microscopically. Metastases were noted in the clavicle, and the dorsal and lumbar vertebrae.

Blumberg³ found a soft gray-green nodular tumor the size of a fist in the right lobe of the liver of a 64 year old man known to have had both lues and diabetes. Metastases to the first, second, and third dorsal vertebrae were present.

The case reported by Catsaras⁴ occurred in a man 65 years of age. A neoplasm in a previously cirrhotic liver had invaded the portal veins into their finest ramifications. Metastases to the neck of the femur caused a pathologic fracture. Bile production in the metastatic tumor cells was noted.

Moon's⁵ case, in a 45 year male negro, also had a pathologic fracture of the right femur. A cirrhotic liver was studded with soft green nodules. Venous invasion by tumor tissue, as well as bile in the metastases, were found microscopically. Other metastases were bilaterally peribronchial.

Geschickter and Copeland⁶ record a case of primary liver neoplasm in a 70 year old male negro, with metastases to pelvis, femur and spine.

Prym⁷ found neoplastic liver cells in a biopsy specimen from a calvarium mass. Bile production and fat infiltration were present. Though no autopsy was done, a large nodular liver was palpable through a relaxed abdominal wall.

Kaufmann⁸ described a case in a man of 33 years who had a tumor in the right lobe of a non-cirrhotic liver, with metastases to pelvic bones, ribs, vertebral bodies, lungs, and abdominal lymph nodes.

Karajanopoulos⁹ found in a man 54 years of age, a tumor in the right lobe of a previously cirrhotic liver, which had metastasized to the manubrium sterni, thoracic vertebrae, and abdominal lymph nodes.

From the Department of Pathology, Beth-El Hospital, Brooklyn, and the Office of the Chief Medical Examiner of the City of New York.

CASE REPORT

A white woman, 29 years of age, was admitted to the orthopedic service of Dr B Koven, at the Beth-El Hospital, Jan 25, 1933, complaining of pain in her left thigh of three months' duration, intermittent but gradually increasing in severity. Terrific pain had confined her to bed for four days before admission.

Her family and past personal histories were negative. No gastrointestinal or urinary symptoms were noted.

The essential findings on physical examination were a shortening of the left lower extremity, outward bowing in the upper third of the corresponding thigh, with crepitation and tenderness at that point. A soft mass the size of a tangerine, adherent to the underlying bony structure, was felt over the eleventh rib below the left scapular angle. No abdominal masses were palpable.

On examination of the blood the hemoglobin estimation was 80 per cent (Sahli), the red blood cells numbered 4,200,000, the white blood cells 7,400 per cu mm with 76 per cent polymorphonuclear neutrophils. The urinary findings, including the examination for Bence-Jones protein, were negative. The blood Wassermann reaction was negative. Nothing unusual was found in the blood chemistry examinations.

Roentgenographic examination demonstrated a pathologic fracture through a neoplastic involvement in the upper third of the left femur, and a similar involvement of the left eleventh rib.

Biopsy of the thoracic mass was done, but the patient died suddenly before a microscopic examination could be made.

Necropsy was performed two hours after death. The body was noted as that of a well developed, fairly well nourished, white woman, about 120 lbs in weight. The left lower extremity was one and a half inches shorter than the right, with abnormal mobility and crepitation at the junction of the upper and middle thirds. A recent 10 cm incision, closed by interrupted cat-gut sutures, through which considerable fluid blood exuded, was present over the eleventh rib in the left scapular line. Nothing found in the head or neck was noteworthy.

Chest The sternum, the right ribs and pleural cavity, and the heart were grossly normal. The left fifth rib 2 cm lateral to the costo-chondral junction was softened in an irregularly circular area 3.2 cm in diameter. The overlying external periosteum and muscular tissue were necrotic, so that slight pressure caused a grumous, dirty, gray-brown material to exude from the rib, the underlying periosteum and parietal pleura were not grossly involved, although expanded a few mm into the pleural cavity. On section the lesion was composed of the grumous material, old blood clot, and a few fine bony spicules. The same rib in the mid-clavicular line presented a fusiform bulge over an area of 2.5 cm caused by an expanding neoplasm in its marrow, similar to the one found in the eleventh rib. The cortex at this point was destroyed and the periosteum moderately thickened. In neither case were the adjacent ribs involved.

The left pleural cavity contained about 200 cc of fluid blood free in the cavity above and below the tumor mass which, displacing periosteum and parietal pleura ahead of it, extended into the pleural cavity from the eleventh rib posteriorly. A small amount of blood was present in several fibrous walled loculi between tumor and lung. Wherever these were separated, the overlying parietal pleura and the periosteum (indistinguishably combined) presented a small, elliptical, smooth edged opening 6 by 3 mm, and several smaller linear openings which led into the tissue composing the tumor mass.

There was a recent operative incision, 10 cm in length, extending parallel to the left eleventh rib posteriorly. To a point 2.5 cm from its vertebral origin, this rib was completely replaced by a fairly soft mass which encroached upon the adjacent ribs. The subcutaneous operative area contained scattered recent hemorrhages and a

layer of cat-gut sutures. Viewed from the pleural surface, the mass was about 7 cm in diameter and projected into the left thorax a distance of 5 cm, displacing thickened parietal pleura before it. There were recent diffuse subpleural hemorrhages over a radius of 10 cm about the tumor. The mass on section was fairly soft, pale green in color, divided into large ovoid lobules by thin fibrous strands. The mass presented several necrotic and occasional faintly outlined hemorrhagic areas.

The eleventh rib was absent in this area, a suggestion of previous periosteum remaining near the still recognizable portion of the rib. The latter had a remarkably thinned cortex, 1 mm in width at the tumor edge, the periosteum raised from its surface by tumor tissue and hemorrhage, and thickened to 1.5 mm. The marrow was soft and brownish and lacked trabecular structure.

FIG 1 Gross photograph of the liver showing the lobulated tumor occupying the greater part of the right lobe. Note the adjacent daughter nodules, the relatively sharp demarcation of tumor from neighboring normal parenchyma, and the absence of cirrhosis in either lobe.

In the three bones in which the marrow and cortex had been invaded by new growth with subsequent pathologic fracture, there was no gross evidence of attempted periosteal or endosteal new bone formation. The periosteum seemed to have been destroyed practically in situ and lifted only to a small degree by the expanding lesion. The adjacent, grossly uninvolved, marrow cavities were neither congested nor softened. After extensive sectioning, the lungs and thoracic lymphatic tissues presented no gross neoplastic involvement.

Abdomen No free fluid or adhesions were present in the peritoneal cavity.

The *liver* measured 24 by 18 by 9 cm and weighed 1400 gm. The outer half of the right lobe was almost completely replaced by a greenish yellow mass, 8.5 cm in diameter, divided by fibrous septa into lobules of an average size of 1.0 to 1.5 cm (figure 1). There were necrotic areas and irregular hemorrhages within these

lobules Adjacent to the larger mass were several similar smaller nodules surrounded by a dark green hepatic parenchyma which was greatly compressed and contained discrete, ovoid, lighter green areas 2 mm in diameter This whole green area was sharply demarcated from the medial half of the right lobe by a narrow fibrous band which puckered the diaphragmatic surface

The remaining hepatic parenchyma was well lobulated and showed no gross changes No cirrhosis was present The portion of Glisson's capsule overlying the tumor was thickened, shreddy, and adherent to the diaphragm The gall-bladder had a thin wall, its mucosa was green, smooth and velvety The biliary ducts were patent throughout and showed no gross alterations of any of their walls The portal and pericholangitic lymph nodes, as well as the retroperitoneal subhepatic tissues were grossly uninvolved The vena cava and portal veins and their larger branches showed no mural or luminal alterations

The *adrenals, kidneys, genitalia* and *pancreas* showed no gross changes

The *gastrointestinal tract* except for mucosal pallor appeared normal There was no enlargement, induration or other change of the mesenteric lymph nodes The thoracic duct and the portal and splanchnic vessels, the vena cava and its tributaries, the aorta and its branches were all grossly normal, including the pelvic vessels and the femoral vessels on both sides to the knee

The *spine* showed no gross changes in the thoracic, lumbar and sacral portions

Extremities There was moderate edema of the left upper anterior thigh The marrow of the left femur from a point 1.5 cm below the midpoint of the junction of the neck and body downward for a distance of 10 cm was completely replaced by rather soft, pale green neoplastic tissue (figure 2) None of the normal trabecular markings remained, the tumor tissue at the edge of recognizable marrow extending into the surrounding soft tissues There was a soft, round, discrete, gray white nodule, 1.2 cm in diameter, 1.8 cm below the upper margin of the greater trochanter and 0.2 cm from its posterior wall The cortex was eroded from within and narrowed, tapering toward the line of a pathologic fracture which extended from a point 7 cm below the upper margin of the greater trochanter downward, forward, and inward, for a distance of 2 cm The tumor tissue here was friable and necrotic, apparently the seat of recent blood extravasation The periosteum was torn through opposite the fracture, and raised by tumor tissue 1.5 cm from the bone on either side There was much hemorrhage into the muscles about the fracture Evidence of healing was absent

The breasts Apart from the occurrence of a small intracanalicular fibroma in the right breast both breasts were normal

Microscopic Examination Liver Throughout the left lobe, and in the right lobe at more than a few centimeters from the mass described above, there are no evident histologic alterations Nearer the mass, the sinusoids become congested so that in a zone of a few millimeters breadth around the mass the picture is one of extreme passive congestion, with red cells present between Kupffer and cord cells, and with the cord cells flattened, frequently separated and showing necrobiotic changes, from granular and vacuolar degeneration to total cyto- and nucleo-rhexis There is in this zone marked distention of bile-capillaries with green granular pigment which gives a positive Gmelin test, and occasionally a positive Turnbull stain In places this pigment outlines the bile capillaries, into the finer intercellular ramifications A few sublobular and larger branches of the hepatic and portal veins are totally filled with tumor thrombi This is observed in the sections taken within 2 cm from the tumor edge, but is not present in sections further removed (figure 3) These thrombi most commonly show either total or partial neoplastic cellular necrobiotic changes, in several places they are permeated by fibrin the tumor cells totally necrotic in the organized and recanalized mass In one section in which all the venous branches are so occluded, two large branches of the hepatic artery are filled with fibrinplatelet

FIG 2 Gross photograph of upper half of left femur showing pathological fracture (A), elevated periosteum and subperiosteal tumor (B), and a solitary nodule in the femoral neck (C)

thrombus, the surrounding hepatic tissue being completely necrotic and heavily infiltrated with partially hemolyzed red cells. The periphery of this sharply outlined area is surrounded by markedly congested normal liver tissue in whose sinusoids are huge numbers of leukocytes. There is no cirrhosis, bile stasis, or cellular infiltration in sections through grossly normal liver except as already noted. Glycogen granules and fat vacuoles (neutral fat) are present regularly and in apparently normal amount in all sections.

The tumor tissue is almost everywhere separated from the surrounding normal tissue by a layer of fibrous tissue, sparsely cellular and poorly vascularized (capillaries), nowhere can any patent transition from the surrounding normal tissue, nor any penetration through the delimiting fibrous tissue be seen, although in places the latter is thinned out almost to single strand thickness. Here and there just beyond the edge of the large mass are small, well circumscribed, round or elongated

FIG 3 Low power microphotograph of tumor thrombus occluding a sublobular hepatic vein. Note the neighboring inflammatory cellular reaction.

masses of similar cells surrounded by fibrous tissue, lying amid the normal hepatic tissue. In all places, however, where such masses do not totally fill such areas in medullary fashion, the delimiting fibrous tissue is seen centrally to be lined by a single layer of flattened endothelial cells, present throughout the periphery except at points where the cell masses extend into the wall. Erythrocytes are present between the cell masses in such incompletely filled areas. In a few places in the large branches of the hepatic vein around the capsule-like delimiting zone, about the large tumor as well as in some large sinus-like spaces within it, are isolated tumor cells, well preserved and stained, free within the lumen and not enmeshed by fibrin, red or wandering cells. Where larger masses are seen, necrobiotic changes and partial lumen occlusion, to a greater or lesser extent, are the rule.

The tumor itself, as well as the smaller daughter nodules, is composed of masses of cells, arranged chiefly in anastomosing strands two cells in thickness (figure 4). There is a marked tendency to radial arrangement of these strands, particularly in the central portion of the large mass, where an occasional vessel is present in the center

of such a radially arranged zone, these vessels, extremely few in number, are arterial in character. There is nowhere any suggestion of true lobular structure, although dense strands of fibrous tissue carrying capillaries and occasional arterioles penetrate the tumor for varying distances from the delimiting fibrous tissue, with which they are connected.

Between the cells of the individual strands one sees very frequently canaliculi partially or completely filled with finely granular pigment varying from a definite green-yellow to a dirty brownish yellow, giving the Gmelin stain regularly but only very occasionally the Turnbull stain. These capillaries are frequently markedly distended, particularly where the cell masses, cut in cross-section, appear as solid alveoli, and they can be traced as fine ramifications between the individual cord cells. Nowhere can any communication with larger ducts be seen, neither portal canal nor bile duct, nor any pigment phagocytosis is apparent in any section. The cord strands

FIG 4 Low power microphotograph of primary hepatic tumor (A) separated from normal liver by poorly vascularized acellular fibrous tissue (B)

are everywhere lined by flattened, stellate-shaped cells resembling in outline and nuclear characteristics Kupffer cells, but being more numerous and having somewhat larger nuclei than is usual in normal cells. In the irregular sinusoidal system between the cords are varying numbers of erythrocytes and scattered leukocytes.

The individual tumor cells are larger than the hepatic cord cells, measuring between 15 to 20 μ . They are well outlined and cuboidal in shape. They have considerable amounts of deeply staining homogeneous acidophilic cytoplasm, and a single round, large, vesicular but hyperchromatic, well-outlined nucleus, with the chromatin peripherally arranged but without well defined nucleolus. Mitoses are extraordinarily rare, there are no amitotic forms, nor do fusion forms or giant cells appear. The cells are remarkably uniform in appearance, except in the smaller intravascular daughter nodules where they are somewhat smaller. Bile canaliculi are absent in such nodules. There is remarkable absence of fatty vacuoles and glycogen granules both in the original growth and its metastases.

The *femur* shows the bone marrow to be replaced entirely by masses of neoplastic

tissue similar to that found in the liver and showing all the elements there described, including bile canaliculi and cord lining cells resembling Kupffer cells (figure 5). The cells are of the smaller variety, in medullary arrangement with small central necrotic areas (figure 6). Only here and there can distinct remnants of marrow

FIG 5 High power microphotograph of femoral metastasis. Note the strand-like two-cell layered arrangement of the neoplastic cells and the elongated Kupffer-like cells (A) separating the cell cords from sinuses. At (B) are two bile capillaries.

FIG 6 Low power microphotograph of femoral metastasis. Note atrophic bone spicule showing decalcified area (A) and lamellae. At (B) is a small vessel resembling a sublobular vein.

reticulum fibers and small patches of erythrocytes, chiefly nucleated, be seen amid the tumor masses. As the line of fracture is approached, the cortical bone trabeculae are narrowed and on their marrow surface show erosions of various sizes, without any apparent osteoclastic hyperplasia, but with a marked and increasing deficiency in lime salts, so that in sections through the fracture itself the trabeculae are totally devoid of such salts, and are separated, with the tumor tissue extending through the line of separation to appear within the periosteum. Likewise toward the fracture from either side, but to a lesser extent than the lime absorptive process, the periosteum is widened, edematous, and very cellular, and the cells fibroblastic in type, at the fracture line, there is a distinct tendency for the cells to be arranged at right angles to the long axis of the bone.

Periosteum and endosteum, indistinguishable in the fracture zone, are infiltrated with moderate numbers of polymorphonuclear leukocytes, elsewhere the lymphocytes predominate in the periosteal infiltrate, while the endosteum is devoid of infiltration. Both the nutrient artery and arterioles in Haversian canals contain tumor cells, but nowhere are there completely plugged vessels.

Sections from areas in the femur not grossly involved, if taken from not more than 3 cm beyond tumor edge, show an occasional tumor nodule or a few cells in vessel and marrow. Active erythropoiesis is apparent.

The ribs show, in all detail, histologic pictures corresponding to those described in the femur. No definite nutrient arterial embolization is demonstrable. Numerous sections of the lungs fail to disclose any tumor tissue within the vessels of whatever order.

This tumor is a primary parenchymal hepatoma, similar in gross appearance to several of those previously reported, though it did not occur in a previously cirrhotic liver. It is the only case with bone metastases reported in a woman, and occurred at 29 years of age, while seven of the nine others were found in patients over 45 years of age. Characteristic extensive vascular invasion and bile production in the metastases were present. As in six of the reported nine cases, evidence of metastases in the lung bed were not found after extensive search. This suggests a specific affinity of the neoplastic cells for the bone marrow in these cases.

The origin of this type of neoplasm is probably in the benign adenoma, whether this be of the congenital type not uncommonly found at the autopsy table or of the type due to proliferation in a parenchyma distorted by cirrhotic changes. That the neoplasm is usually single rather than multicentric in origin is suggested by the frequency with which only a right lobe neoplasm is found (five of the eight cases reported in detail, including our own).

The tumor acts like an organ rather than tissue in its metastases, these present all the structures of the normal liver, including cords of cells in double rows, intervening capillaries, and Kupffer cells. Bile and bile canaliculi are found, the former not undergoing phagocytosis by the Kupffer cells. That the metastasis may have the physiologic activity of the original organ is suggested by the bile formation present in our case. That such functions are not, however, completely the counterpart of the original organ, either in the primary neoplastic focus or the metastases, is suggested by the absence of glycogen granules and fat within the tumors, while the normal liver contained both.

From the standpoint of the clinician, attention should be directed toward the liver in those cases coming under observation with metastatic lesions, espe-

cially those of spine and femur, typically expanding in character and lacking new bone formation, in which the usual primary sites, lung, prostate, thyroid, breast and kidney have been excluded. The liver is likely to escape serious attention because of the tendency of a primary hepatoma to involve one lobe, thereby not interfering with liver function tests, rarely producing jaundice or ascites, and not usually causing appreciable hepatic enlargement or nodulation. Thorotrast injection may aid in outlining such tumors which are most frequently few in number, fairly well demarcated, and sufficiently large to yield shadows if outlined.

SUMMARY

A case of primary liver carcinoma (hepatoma) with bone metastases is reported. Nine cases from the literature are collected and described briefly. Evidence is presented to indicate that this type of neoplasm is organoid rather than histioid, and shows in its metastases morphologic evidence of its original physiologic function. Attention is called to the liver as a focus for metastatic bone neoplasm in obscure cases.

The authors desire to express their thanks to Dr. B. Koven, attending orthopedist at the Beth-El Hospital, for permission to use the clinical data of this case, and to Dr. Thomas A. Gonzales, acting Chief Medical Examiner of the City of New York, for permission to use the pathologic data of this autopsy performed, as assistant medical examiner, by one of us (M. J.).

ELECTROCARDIOGRAPHIC CHANGES WITH PERFORATED
DUODENAL ULCER, A CASE REPORT¹

By LEMUEL C MCGEE, PH D, M D, HAROLD A CONRAD, M D, and
ANGUS K WILSON, M D, *Elkins, West Virginia*

C M, male, coal-miner, aged 39 years, entered the hospital one Sunday morning in shock and semi-coma. The history, obtained from his family, was that he had been seized with severe upper-abdominal pain while walking from one room to another in his home 12 hours previously, and that he had collapsed immediately. There had been no radiation of the pain to the sternum. He had become quite short of breath following the onset of pain and could not sleep. The pain had diminished but did not disappear. The next morning, 10 hours after onset of symptoms, a physician was called and the patient received a hypodermic, presumably of morphine. Some time afterward he started on a 50 mile trip, by ambulance, to the hospital.

Just at the time of his arrival, the patient had a recurrence of the excruciating pain in the epigastrium. He exhibited extreme dyspnea, dehydration, cyanosis and a truly rigid abdomen. After saline and glucose had been administered intravenously, the abdomen became pliable and the patient recovered somewhat from shock. An electrocardiogram (figure 1) was taken which presented inversion of T-waves in Leads II and III with elevation of the S-T interval in those leads as well as in Lead IV.

The sudden onset of pain in the epigastrium and the finding of marked rigidity of the muscles of the upper abdomen pointed to acute intra-abdominal disease with peritoneal irritation. The abdominal wall was not rigid for the subsequent few hours and during this time the patient vomited. A tentative diagnosis of either perforated duodenal ulcer or acute pancreatitis was made. When the cardiogram was developed, there arose the possibility of coronary occlusion with posterior surface infarction. The white blood count was 9,900 cells per cu mm. The cervical veins were markedly distended and for a period of two hours there was definite pulmonary edema and a frothy sialorrhea. Heart sounds were faint, with a rate of 140 per minute. The red cell count was 4,740,000 and the blood Kahn was negative. Because of the lapse of more than 12 hours since the onset of the catastrophe and the persisting shock of the patient, the chance offered by surgery was described to the family as being very small. The family wished to have no surgery attempted and this was agreed to by the consulting surgeons and physician.

The patient was removed to a room in the hospital where, unfortunately, electrical interference makes the recording of the electrocardiogram very unsatisfactory, and hence no effort was made to repeat the tracing. A few hours later a third paroxysm of epigastric pain developed and with it, the upper abdomen again became exceedingly rigid for a few hours. The pain at this time extended down in to the left flank. The vomiting continued.

In the periods between throes of severe pain with collapse, the blood pressure rose to 130 systolic and 80 diastolic from a brachial pressure too low to be read immediately after admission. The patient's temperature was, for the most part, between 99° and 100° F rising but once to 100.6° F.

The patient recalled that for the previous six months he had had recurring attacks of rather severe epigastric pain with shortness of breath, and voluntarily stated that his abdominal muscles would become quite "hard" during the attack. The periods of distress were too numerous to count and they appeared only when he was working in the mines or when walking to or from his home. He was positive in

* Received for publication June 20, 1936.

the assertion that the discomfort was related to exertion, that the pain never extended into the chest or shoulders and that resting a few minutes provided relief. He had never observed that taking of food relieved him but had noticed that the pain was more apt to appear one to three hours after eating than at any other time. There had been no nocturnal distress but he had slept, by preference, on two pillows. For the previous four weeks he had had a cough and had noted faintness and giddiness. He had lost 10 pounds in weight. He drank five or six cups of coffee daily and had had to void urine twice each night. He had stopped work two weeks before because of

FIG 1 Electrocardiogram taken at time of admission. Note low T_2 , inverted T_2 and elevated S-T interval in Leads II and III.

marked dyspnea and weakness. He had been on no medication. In the past he had had a gonorrheal urethritis, a crushed foot, a broken nose, and a broken left arm. He had lost two wives from what had been diagnosed as pulmonary tuberculosis. His father at the age of 75 years, had died after a chronic "gastric" complaint of several years' standing.

The abdomen became quite distended the day following the patient's admission. He received supportive treatment. He died after 70 hours in the hospital. The intriguing history, pointing to myocardial disease, and the terminal illness with death

from evident peritonitis, prompted an autopsy to ascertain whether there were two disease processes present.

The body was that of a man of about 170 pounds, appearing to be older than 39 years. Three liters of a greenish brown fluid were removed from the peritoneal cavity. The peritoneum was generally acutely inflamed. The omentum and superficial coils of bowel were matted with an abundant purulent exudate and thick fibrin. The duodenum was surrounded by both fibrin and firm fibrous adhesions extending to every adjacent structure. The fundus of the gall-bladder covered a perforation in the duodenal wall. The gall-bladder itself was intact but covered with exudate and fibrin. When the duodenum was opened, two typical, chronic "kissing" ulcers were found, the upper one alone having perforated. This ulcer measured about 5 mm by 6 mm in diameter and had thickened margins (figure 2).

The thoracic cavity contained no significant abnormalities. The pericardial sac was normal. The heart weighed 360 grams and the left ventricular wall was 15 mm thick midway between base and apex but otherwise all measurements were well within normal limits. The coronary vessels were healthy in appearance except for a small atheroma in the left coronary about 2 cm from the orifice. Careful dissection of these vessels revealed no occlusion. Extensive sectioning of the myocardium revealed no infarction, either old or recent. There were no other noteworthy findings at the autopsy. The histological study confirmed the interpretation of the gross pathological findings.

An occasional striking association between disease of the gall-bladder and symptoms referable to the heart has been noted in the past 30 years^{1,2}. Carmichael³ noted a bradycardia in a patient having an obstructed cystic duct. The periods of bradycardia were observed three separate times, coinciding with strong contraction of the gall-bladder muscle. Tennant and Zimmerman,⁴ in a statistical study of 1,600 autopsies, found "a significant association between the occurrence of heart disease in general and gall-bladder disease". Fitz-Hugh and Wolferth⁵ reported six patients with cardiac complaints and abnormal electrocardiographic tracings who had gall-stones removed. A few weeks after the operation, the electrocardiographic abnormalities became normal in each patient. Willis and Fitzpatrick⁶ found, in a series of 596 patients, a striking improvement in the cardiovascular condition after treatment for chronic disease of the gall-bladder, even in the group (229 patients) having organic disease of the cardiovascular system. The association between peptic ulcer and cardiac symptoms is undoubtedly less frequently noted. Barker, Wilson and Collier⁷ reported, in 1934, an instance of perforated duodenal ulcer simulating the clinical picture of acute coronary occlusion.

The patient in the present report presented cardiac symptoms prior to the terminal illness. There was no evidence of chronic gall-bladder disease. It is obvious from the history and the finding of scar tissue about the duodenum that the patient had previously had "formes frustes" perforations of one or both the chronic ulcers. In the terminal catastrophe, the fundus of the gall-bladder had been employed to plug the perforation after three distinct leaks of the duodenum with a collapse accompanying each fresh emptying of duodenal contents. The electrocardiographic changes noted may have resulted from, (1) shock and low systemic blood pressure with insufficient oxygenation of the cardiac musculature, (2) embarrassment of circulation due to displacement of the heart by the elevated diaphragm, or (3) a reflex change in cardiac circulation and function initiated by the inflammatory process about the duodenum and gall-bladder.

A common experiment made upon frogs in the physiology laboratory is the production of a bradycardia or even cardiac standstill by light taps on the abdomen. This effect is lost when the vagus nerves are severed. There exists

FIG 2 Photograph showing "kissing" duodenal ulcers. The ulcer on the left had perforated.

ample clinical evidence of the change in cardiac behavior in man initiated by reflexes arising from diseased abdominal viscera. However, it seems to the authors that the physiological changes accompanying shock in this patient were

likely of more import to the heart than reflexes from the acutely inflamed abdominal viscera. Because of the over-emphasis often placed by physicians upon the changes of the electrocardiogram in clinical practice, the findings in this patient are noteworthy. He had no serious heart disease that could be demonstrated after careful anatomic dissection.

Because of the occasional transient, non-specific R-S interval and T-wave changes in a variety of conditions, it is to be regretted that serial tracings were not available.

EDITORIAL

THE AWARD OF THE JOHN PHILLIPS MEMORIAL MEDAL

THE John Phillips Memorial Medal has been awarded for 1937 to Dr Richard E. Shope, of the Rockefeller Institute for Medical Research, at Princeton, New Jersey. The award is based on Dr Shope's researches with filterable viruses which are regarded as outstanding in medical biology. Among these are (1) the discovery of a tumor of rabbits, which now bears his name, and the demonstration that this tumor, which has many of the characteristics of a malignant neoplasm, is due to a filterable virus, (2) his contributions to the etiology and epidemiology of mad itch in cattle and the establishment of the identity of the virus causing this condition in cattle and that causing pseudorabies in swine, (3) the demonstration that swine influenza is not due to a single agent but is caused by an infection with a filterable virus and a hemophilic bacillus, (4) the production of evidence to focus attention on the possibility that the swine virus has at some time in the past been the agent in human influenza.

THE CHEMOTHERAPY OF HEMOLYTIC STREPTOCOCCUS INFECTIONS

THE report by J. G. Arnold, Jr., in this number of the *ANNALS*, of a case of grave hemolytic streptococcus infection which recovered under treatment with prontosil brings to the attention of our readers a new and promising chemotherapeutic agent.

The report by Domagk¹ in 1935 that the dye "prontosil" exerts a definite protective action in the case of mice infected with virulent hemolytic streptococci aroused widespread interest and stimulated many other workers to investigate the action of this substance. Domagk's findings have been confirmed and extended, particularly by Levaditi and Vaismen,² Colebrook and Kenny,³ Buttle, Gray and Stephenson,⁴ and Long and Bliss.⁵ This preparation is of special interest since, with the exception of optochin in pneumococcus infections, it is the only instance of a drug which exerts a specific action on a bacterial infection.

² LEVADITI, C., and VAISMEN, A. Action curative et preventive due chlorhydrate de 4'-sulfamido-2, 4 diamino-azobenzene dans l'infection streptococcique experimentale, *Compt. rend. Acad. d. sc.*, 1935, cc, 1694.

³ COLEBROOK, L., and KENNY, M. Treatment of human puerperal infections, and of experimental infection in mice, with prontosil, *Lancet*, 1936, i, 1297.

⁴ BUTTLE, G. A. H., GRAY, W. H., and STEPHENSON, D. Protection of mice against streptococcal and other infections by p-Aminobenzene-sulfonamide and related substances, *Lancet*, 1936, i, 1286.

⁵ LONG, P. H., and BLISS, E. A. Para-amino-benzene-sulphonamide and its derivatives, *Jr. Am. Med. Assoc.*, 1937, cxviii, 32.

Prontosil is the hydrochloride of 4-sulfamido 2, 4 diamino-azo-benzene. It is poorly soluble. "Prontosil soluble" is a related substance with a more complicated structural formula which is more soluble and is suitable for parenteral injection. Under the influence of reducing agents these compounds are decomposed *in vitro* into para-amino-benzene-sulphonamide ("prontylin") which is believed to be the active ingredient of these substances. It is thought that a similar reduction is brought about in the body of animals treated with prontosil by the action of the streptococci themselves.

These workers in general agree that after intraperitoneal inoculation with highly virulent strains of beta-hemolytic streptococci, mice suitably treated with any of these substances recover or materially outlive the untreated control animals. Thus in experiments reported by Long and Bliss, untreated control animals receiving from 10 to 100 M.L.D. of culture invariably died on the first or second day, whereas the six treated animals in one series survived from six to 31 days, and in another series all six recovered. These results were obtained even though treatment was begun eight hours after infection and the mice gave positive blood cultures with 100 to 1000 or more colonies per c.c. of blood. Treatment had to be continued for some time or relapse and death occurred. Some difference was noted in the susceptibility of various strains of streptococci to the action of the drug. The results were much less definite when strains of low virulence were used.

The mode of action of the drug is not definitely known. Prontylin (but not prontosil) exerts a moderate bacteriostatic activity when added to cultures of beta-hemolytic streptococci, even in the presence of serum. The serum of animals treated with prontylin also shows an inhibitory effect on the growth of streptococci. No definite bactericidal effect, however, has been noted. Long and Bliss found that in their treated mice films from the peritoneal exudate made 24 to 72 hours after infection showed that active phagocytosis of the streptococci was taking place. At the same time the number of viable organisms in a drop of peritoneal exudate progressively diminished. In untreated mice this was not observed. They believe that the drug injures or affects the organisms in such a way that they become susceptible to phagocytosis. They could not confirm the observations of Levaditi and Vaismen that the drug inhibited the formation of capsules by the organisms. The drug showed relatively little or no protective power against the other species of organisms tested.

Favorable results have also been reported particularly in German and French journals from the use of these drugs in the treatment of human infections. In general these clinical studies were not carefully controlled and are less convincing than the animal experiments. Colebrook and Kenny treated 38 cases of puerperal infection with hemolytic streptococci and reported a mortality of 8 per cent as compared with an average mortality of 22 per cent in cases treated by other methods during the preceding four

years Several patients who recovered had had a severe type of infection in which the prognosis would have been grave Long and Bliss reported favorable results in a series of 19 cases of beta-hemolytic streptococcus infection of various types, including several cases of erysipelas and scarlet fever One patient with otitis media and mastoiditis who recovered had shown a positive blood culture with over 2000 colonies per c c of blood There were two deaths, one nine hours and one 22 hours after treatment was started Both groups of workers were conservative in their claims as to the efficacy of the treatment

Thus far relatively few untoward effects have been reported A transient febrile reaction may follow the parenteral injection of large doses of the drug It is readily absorbed both from the tissues and from the gastrointestinal tract It is excreted quite promptly in the urine, and in cases with impaired renal function the possibility of a dangerous accumulation in the body fluids must be kept in mind Signs of mild renal irritation have been noted in a few cases In three cases Colebrook and Kenny observed cyanosis due to sulphemoglobinemia, but all recovered

This work is still in the experimental stage, and needs to be confirmed The number of patients who have been treated with these drugs is very small, and no series of cases has been adequately controlled The possibility of serious untoward effects has not been excluded It is, therefore, quite impossible to draw any definite conclusions as to the value of this treatment, but the results which have been reported seem sufficiently promising to warrant continued trial under conditions which permit accurate observation, together with adequate controls

P W C

REVIEWS

Principles of Biochemistry By ALBERT P. MATHIJS, Andrew Carnegie Professor of Biochemistry, University of Cincinnati. x+512 pages, 23.5 × 16.5 cm. William Wood and Company, Mt. Royal and Guilford Aves., Baltimore, Maryland. 1936. Price, \$4.50.

Students of the biological sciences have long been acquainted with the author and his familiar and authoritative "Physiological Chemistry," since he has been teaching biochemistry to medical students and contributing to experimental research for forty years. The present volume, however, is shorter and written in a different style—in fact it is an entirely new book. It is written in six parts, namely, Glucides, Lipides and Proteins which constitute the major portion of the book, and Blood and Connective Tissues, Vitamins and Hormones, and Energy Metabolism. The approach to certain subjects, especially the discussion of the carbohydrates, proteins and fats, is somewhat unusual in that the description of their more fundamental chemical principles is smoothly blended with a discussion of the factors influencing their digestion and metabolism, both under normal and pathological conditions. A valuable addition to the subject matter is the discussion of clinical material.

Written in a most interesting manner, the book is very readable and is a good text to use along with the usual set of lectures which are given to medical students. This volume should be especially valuable to the student or young doctor preparing for the board examination, or to doctors or workers in science generally who wish to review and bring up-to-date their knowledge of biochemistry especially as it concerns the human body. The younger student with a flair for research will find its pages a veritable storehouse of enticing problems awaiting solution. The author states that he has omitted "almost all references to the literature as this is not intended to be a reference handbook." This the reviewer feels is to be regretted. The modern medical student is interested in the experimental development of biochemistry, but has had little if any training in consulting the original literature, and certainly receives insufficient assistance along this line while in medical school. It seems unfortunate that Dr. Mathijs, with his great personal knowledge of the historical background of biochemistry, has not made this information available to the student by means of an organized bibliography. This defect, however, is insignificant in comparison with the general excellence of the book.

It was the purpose of the author to "correlate and synthesize the numerous facts, so that they will appear not as an inchoate assembly of facts, but as making part of a great science which reveals the finer structure and coordinated chemistry of the human body." This purpose, in the reviewer's mind, has been well attained.

E. G. S.

Textbook of Surgery By JOHN HOMANS. 4th edition. 1267 pages, 25.5 × 17.5 cm. Charles C. Thomas, Springfield, Illinois, and Baltimore, Maryland. 1936. Price, \$8.00.

Through its four editions since 1931, this book has kept the characteristics intended by its author, namely, an edited reflection of the teaching in the surgical department of the Harvard Medical School developed by Harvey Cushing and his associates. Accordingly it is an almost unique weld of the historical development of surgery, the dogmatism necessary for student teaching and present surgical beliefs.

The present edition differs from the third by the inclusion of chapters on Amputations and Plastic Surgery. This new material is well up to the standard of the remainder of the book.

E. M. H.

The Thyroid—Surgery, Syndromes, Treatment By E P SLOAN, M D 475 pages, 26 × 17.5 cm Published by Charles C Thomas, Springfield, Illinois, and Baltimore, Maryland 1936 Price, \$10.00

This book represents the experience and judgment derived from the observation of 20,000 patients in a thyroid clinic. Although the author states that the book is not intended to be encyclopedic, no phase of his subject has been neglected. The bibliography contains 254 names. The authors of the bibliography are indexed and there are indices of subjects and names. Chapters on the parathyroid glands and the thymus are also included.

In such a monograph there is necessarily much that a reviewer may find to which exception might be taken as to fact or interpretation of fact, but such disagreement in opinion in no way detracts from the value of this book. One might point out that recent work on the lymphatics of the thyroid could have been discussed with advantage in particular connection with some of the author's own ideas. Considerable emphasis is given to an unknown substance which for the purpose of discussion the author calls "thyrom," pictured as the active principle contained in the thyroxin molecule which differentiates thyroxin from iodine. The discussions of the underlying basis of symptoms is interesting. The chapters on surgical treatment are particularly complete with a well presented exposition of the surgical anatomy. In such a well finished production this reviewer regrets to see the use of such a hybrid as "subnormalcy" which the author uses in place of more acceptable wording.

This book will be found a valuable addition to the literature on thyroid disease.

E M H

Modern Treatment of Diseases of the Respiratory System By A LISLE PUNCH, M B, M R C P, and F A KNOTT, M D, M R C P, D P H 295 pages, 14 × 20 cm, illustrated P Blakiston's Son and Co, Inc, Philadelphia 1936

The authors as stated in the preface, have intended this book primarily for the general practitioner and the medical student who is just beginning his hospital training.

From this standpoint they have achieved their purpose admirably. The text is concise and yet comprises an adequate survey of the field of pulmonary disease. The authors have included painstaking descriptions of various clinical procedures, such as the technic of thoracentesis, pneumothorax, etc., and have included illustrations and descriptions of apparatus. The roentgenographic plates are exceedingly good and abundant, and the pathology is clearly pointed out, thus adding materially to the value of the book.

H V L

The Diagnosis and Treatment of Diseases of the Peripheral Arteries By SAUL S SAMUELS, A M, M D 260 pages, 51 illustrations, 22.25 × 15 cm Indexed Oxford University Press, New York 1936 Price, \$3.50

This volume is not an exhaustive treatise on the subject matter of the title. A classification of diseases of the peripheral arteries is presented and methods of examination and diagnosis are described. Thromboangitis obliterans is discussed at some length. The author considers the use of tobacco, especially cigarette smoking, to be a very important factor in the progress of the disease. He emphasizes his belief in the efficacy of intravenous hypertonic saline injections plus rest and postural exercises in the treatment of this condition, and finds most other methods that have been advocated to be of doubtful use or even harmful. There is very little discussion of the other methods of treatment. There is a briefer discussion of arteriosclerosis obliterans and diabetic gangrene. Very short chapters on Raynaud's disease, erythro-

melalgia and essential thrombophilia are included. There is also a chapter on the medico-legal aspects of peripheral arterial disease.

The reviewer does not feel that this book can be recommended as a well balanced discussion of the subject matter of the title. It does forcefully present the author's views on the treatment of thromboangitis obliterans.

W S L

Tuberculosis. By GERALD B WEBB, M D. 205 pages, 17 × 11.5 cm. Paul B Hoeber, Inc., New York. 1936. Price, \$2.00.

Dr Webb's book is the first in the series of Clio Medica limiting itself exclusively to one disease entity and as such sets a noteworthy example for others that will surely follow. In dealing with this age-old disease, so intimately tied up with the history of medicine in general, Dr Webb has divided the subject into its various phases. Practically every chapter takes up just one aspect of the subject of tuberculosis and discusses it in its entirety, chronologically. It is thus possible to get a complete picture of the history of any one phase of the disease by reading the appropriate chapter.

The few illustrations and charts are well chosen and the quotations extremely interesting. It might be worthwhile to translate some of the quotations which are presented in the original. The bibliography and the index of names increase the value of this book. This most recent contribution to the history of tuberculosis will be welcomed by all students of the disease. It is scholarly and informative and yet at the same time readable and entertaining.

COLLEGE NEWS NOTES

LIFE MEMBER

Dr Samuel A Vogel (Fellow), Buffalo, N Y, has become a Life Member of the College under date of January 25, 1937

GIFTS TO THE COLLEGE LIBRARY

The following gifts to the College Library of publications by members are gratefully acknowledged

Books

- Major Daniel B Faust (Fellow), (MC), U S Army, one autographed book, "Diet Manual, Letterman General Hospital",
Dr Jacob Gutman (Fellow), Brooklyn, N Y—9th Supplement to "New Modern Drugs",
Dr J J Singer (Fellow) and Dr Evarts A Graham, F A C S, St Louis, Mo—one autographed book, "Surgical Diseases of the Chest" (with Harry C Ballou)

Reprints

- Dr Miles J Breuer (Fellow), Lincoln, Nebr—1 reprint,
Dr E H Drake (Fellow), Portland, Maine—3 reprints,
Lt Col Frederick H Foucar (Fellow), (MC), U S Army—1 reprint,
Dr Salvatore Lojacono (Fellow), Tucson, Ariz—1 reprint,
Dr John H Musser (Fellow), New Orleans, La—27 reprints,
Dr E Sterling Nichol (Fellow), Miami, Fla—7 reprints,
Dr William H Ordway (Fellow), Mount McGregor, N Y—3 reprints,
Dr Carleton B Peirce (Fellow), Ann Arbor, Mich—13 reprints,
Dr Horace K Richardson (Fellow), Stockbridge, Mass—3 reprints,
Dr J J Singer (Fellow), St Louis, Mo—20 reprints,
Dr Willard J Davies (Associate), Rockville Centre, N Y—2 reprints,
Dr Everett C Fox (Associate), Dallas, Tex—12 reprints,
Dr Louis L Perkel (Associate), Jersey City, N J—1 reprint
-

KENTUCKY MEMBERS HELD ANNUAL MEETING

The Kentucky Fellows and Associates of the American College of Physicians held their annual meeting at Lexington, Ky, January 9, 1937 Dr Ernest B Bradley (Fellow), Lexington, President of the College, Dr C W Dowden (Fellow), Louisville, College Governor for Kentucky, and Dr J W Scott (Fellow), Lexington, Chairman for Arrangements, sponsored the meeting Thirty-five members of the College were in attendance, in spite of extremely inclement weather The afternoon program was as follows

- Dr R W Sparkman (by invitation) "Quantitative Estimations of Glycosuria Following Intravenous Administration of Glucose",
Dr R B Warfield (by invitation) "Calcinosis Universalis",
Dr Ernest B Bradley (Fellow) "An Unusual Type of Lymphosarcoma",
Dr John Harvey (Fellow) "Contracted Kidneys Due to Pyelonephritis",
Dr C H Fortune (Fellow) "Edema of Obscure Type"

In the evening a dinner was held at the LaFayette Hotel. The entire meeting has been reported as a very successful, beneficial and enjoyable one. The policies and practices of the College are more thoroughly understood by the members at large, members are given a closer contact with one another from the social angles of these local meetings, and interest is inspired in the activities of the College.

Dr Henry W Grote (Associate), Bloomington, Ill, has accepted an appointment as head of the Roentgenological Department of the Brokaw Hospital of Bloomington.

Mr William Albert Widmer, head of the medical sales department of the J B Lippincott Company, publishers, died suddenly early in January. Mr Widmer was known widely in the medical profession, because for many years his face was a familiar one at the book exhibits of the J B Lippincott Company at medical meetings all over the country. In fact, Mr Widmer probably was the dean of medical exhibitors, for he was among the very first to initiate the plan of making conveniently available to doctors for examination books or other medical products by displaying them at the annual gatherings of various medical societies.

Mr Theodore A Phillips, for some years associated with the W B Saunders Company, publishers, has been appointed successor to Mr Widmer, with the J B Lippincott Company.

Dr John H Musser (Fellow), New Orleans, was a guest speaker at a meeting of the San Diego (Calif) Academy of Medicine, December 3.

The Stanford University School of Medicine, San Francisco, presents each winter a series of popular medical lectures, given on alternate Friday evenings. Among contributors to the fifty-fifth series now in progress were the following:

Dr Benjamin W Black (Fellow), Oakland, January 22, "The County Hospital and the Public",

Dr William C Voorsanger (Fellow), San Francisco, February 5, "Recent Advances in the Treatment of Tuberculosis".

Dr Samuel A Levine (Fellow), Boston, discussed "Pitfalls in the Diagnosis of Heart Disease" before a joint meeting of the Medical Society of the District of Columbia and the Washington Heart Association on December 9.

Dr John W Ferree (Associate), Bluffton, Ind, has been appointed chief of the recently created bureau of local health administration, Indiana State Division of Public Health.

Dr Donald Gregg (Fellow), Wellesley, Mass, is President of the Massachusetts Society for Mental Hygiene.

On December 16, 1936 a meeting of the Rhode Island Fellows and Associates of the College was held at the John M Peters House of the Rhode Island Hospital. At the meeting, Dr Charles F Gormly was elected Chairman, and Dr Cecil Dustin, Secretary. Dr Guy W Wells was elected Chairman of a program committee of

four members Dr Wells, Dr Alex M Burgess, Governor of the College for Rhode Island, and the Chairman and Secretary of the Rhode Island group, ex-officio Dr Jacob Fine of the Beth Israel Hospital of Boston was the guest speaker of the occasion and gave an interesting account of experimental work on the effect, upon the absorption of gases in the body, of inhalation of concentrated oxygen mixtures

Dr Henry A Christian (Fellow), Hersey Professor of the Theory and Practice of Physics at Harvard University Medical School will prepare and edit future revisions of Osler and McCrae's "The Principles and Practice of Medicine"

Dr N Thomas Saxl (Fellow), New York City, has been appointed Medical Director of the Police Athletic League, an organization formed by the Juvenile Aid Bureau of New York City, for the purpose of providing suitable physical and recreational activities for children with delinquent tendencies

Dr Henry Snure (Fellow) and Dr George Maner presented a paper on "Roentgen-Ray Evidence of Metastatic Malignancy in Bone" before the Radiological Society of North America, on November 30, at Cincinnati, Ohio Their exhibit illustrating their paper won first award in the scientific exhibits

NEW LIFE MEMBERS

The following have become Life Members of the American College of Physicians on the dates indicated

Dr Manfred Kraemer, Newark, N J	January 9, 1937
Dr James W Hunter, Jr, Norfolk, Va	January 9, 1937
Dr Herbert B Smith, Corning, N Y	January 11, 1937
Dr Fresenius Van Nuys, Weston, Mass	January 12, 1937
Dr George M Settle, Baltimore, Md	January 12, 1937
Dr Edward B Vedder, Washington, D C	January 13, 1937
Dr Robert A Peers, Colfax, Calif	January 16, 1937
Dr Joseph Condit, Pasadena, Calif	January 18, 1937
Dr Charles W Stone, Cleveland, Ohio	January 18, 1937

CONDENSED MINUTES OF THE BOARD OF REGENTS

PHILADELPHIA, PA

December 13, 1936

The Board of Regents of the American College of Physicians met at its Philadelphia headquarters, 4200 Pine Street, at 10 00 a m, December 13, 1936, with Dr Ernest B Bradley, President, presiding The following were present

Ernest B Bradley, President
 James H Means, President-Elect
 O H Perry Pepper, First Vice President
 David P Barr, Second Vice President
 Walter L Bierring, Third Vice President
 William D Stroud, Treasurer
 William Gerry Morgan, Secretary-General
 Sydney R Miller

George Morris Piersol
 Robert A Cooke
 Jonathan C Meakins
 Hugh J Morgan
 James E Paullin
 James Alex Miller
 Francis M Pottenger
 Maurice C Pincoffs
 Charles H Cocke

and Mr E R Loveland, Executive Secretary, acting as secretary of the meeting. The Executive Secretary read abstracted Minutes of the Detroit meeting of the Board of Regents, which were approved as read. He then read in full the Minutes of the meeting of the Executive Committee held at Philadelphia on June 21, 1936.

Upon motion by Dr James E Paullin, seconded by Dr George Morris Piersol, and regularly carried, it was

Resolved, that the Board of Regents approve of the action of the Executive Committee, and that their Minutes be adopted.

The Executive Secretary then presented the following communications

- (a) A letter from Dr E L Tuohy, Governor for Minnesota, dated June 29, 1936, recommending the election of an additional Governor for the State of Minnesota, this additional Governor to take over the southern part of Minnesota and, perhaps, the State of South Dakota.

Discussion developed the opinion that it should be possible for Dr Tuohy to obtain adequate information about candidates in southern Minnesota through members of the Mayo group in Rochester, and that it would be better to handle the situation in this way for the present time.

Upon motion by Dr James E Paullin, seconded by Dr George Morris Piersol, it was

Resolved, that Dr Tuohy's communication be acknowledged, and the suggestion concerning handling the Minnesota situation without an additional Governor communicated to him.

- (b) Following advice that the law required the College to have a Certificate of Authority as a Corporation foreign to the State of Pennsylvania to operate its main office in this State, proper steps had been taken to obtain an official Certificate of Authority from the State Department of Pennsylvania.
- (c) Communications from the Social Security Board. Forms had been filled out and returned, with the explanation that the College is a Corporation organized "not for profit." Although no reply or decision had been received from the Social Security Board, the Executive Secretary expressed the opinion that the College would not be subject to the regulations of the Social Security Act.
- (d) A communication from the U S Post Office granting a reclassification of the ANNALS OF INTERNAL MEDICINE, and reducing the mailing rates to 1½¢ per pound, resulting in a considerable saving in the future on postage.

President Bradley then presented a letter, dated July 23, 1936, from Dr George Crile, Chairman of the Board of Regents of the American College of Surgeons. Dr Crile asked whether it would be possible for the American College of Surgeons and the American College of Physicians to jointly consider a plan to eliminate the indiscriminate use of the words "Physician and Surgeon" by men without special training in a special field, and to have each doctor designated in his practice as "Physician," "Surgeon," "Medical Specialist," "Surgical Specialist" or "General

Practitioner" Dr Crile suggested that the General Practitioner should limit his practice to diagnosis, medicine, minor surgery, emergency work and non-operative obstetrics, that the two Colleges should work together to influence the authoritative bodies to bring this change. Dr Bradley had replied, stating that he had no authority to act, but that the matter would be referred to the Board of Regents, who might be disposed to appoint a committee to confer with a committee from the American College of Surgeons. A further communication from Dr Crile indicated that such a committee had been appointed by his organization.

After general discussion, Dr James Alex Miller moved, and Dr James E Paulin seconded the following resolution, which was carried:

Resolved, that the President be authorized to appoint a committee of from one to three members to confer with a similar committee of the American College of Surgeons in any matters in which both bodies may be interested.

Dr William Gerry Morgan, Secretary-General, reported the following deaths since the last meeting of the Board of Regents:

Master

Anders, James M	Philadelphia, Pa	August 29, 1936

Smith, Webster S	Dayton, Ohio	January 30, 1936

President Bradley stated that he would appoint a committee later on to draw up suitable memorials for those who had been past presidents or governors of the College

The following memorial prepared by Dr S Marx White was read by the Secretary-General, Dr Morgan, and a resolution adopted providing that it be spread upon the Minutes of the Board of Regents and a copy sent to Dr Brown's widow

GEORGE E BROWN

"Dr George Elgie Brown was born at Grand Rapids, Michigan, July 16, 1885. He received the degree of M D in 1909 from the University of Michigan, following which he served two years' internship at the Northern Pacific Hospital, Brainerd, Minnesota. He was married to Irma Parker, July 12, 1911. During the years of his practice in internal medicine at Miles City, Montana, from 1911 to 1921, he carried on special studies at Harvard University for five months in 1914, studied organic chemistry in the summer of 1916 at Johns Hopkins University, Baltimore, and was with the Rockefeller Foundation in France in 1918 and 1919. He was appointed first assistant in medicine at the Mayo Clinic, Rochester, Minnesota, February 1, 1921, and made an associate in medicine, April 1, 1922, later becoming head of a section in medicine at the Mayo Clinic, and associate professor of medicine, in the Mayo Foundation, University of Minnesota. He filled these appointments with distinction until his death. Fellow of the American Medical Association and of the American College of Physicians, he was a member of the Board of Regents of the College from 1927 to 1933. He was also a member of the American Society of Clinical Investigation, the Central Society for Clinical Research, the Alumni Association of the Mayo Foundation, the Association of American Physicians, the Central Inter-urban Clinical Club, the Minnesota Society of Internal Medicine and the Southern Minnesota Medical Association. He was a member of Phi Rho Sigma fraternity and of Sigma XI honorary fraternity.

"During the two years' internship in Brainerd and the ten years of practice in Miles City, he exhibited unusual initiative and industry in clinical research. His first paper, entitled 'The Practical Use of Tuberculin in Diagnosis,' was published in 1911 as a result of work done during his internship. Ten more papers, the majority of them in first-class journals, were published during the ten years of active practice in Montana. During these latter years also he was known to have exhibited much ingenuity in the construction of x-ray apparatus for his own use in practice. During the period of nearly fifteen years of association with the Mayo Clinic, the contributions to medical literature bearing his name or as co-author number 115. His contributions revealed marked originality and by them he became one of the leading authorities in this country, particularly in diseases of the vascular system and in arterial hypertension. His standard cold-pressor test for measuring variability in blood pressure, published with E A Hines, Jr, and his contributions with several members of the Mayo Clinic staff have served to break new paths in the ready recognition of hyper-reactors in essential hypertension and in the surgical treatment of certain of the later stages of the disorder. The 200-page monograph on thrombo-angitis obliterans bearing his name is of great practical value in that it serves to show that correct diagnoses can be made without special methods in more than 95 per cent of the cases of the vascular diseases affecting the extremities. His initiative and drive, his helpful, cheerful friendliness and practical, wise counsel will be greatly missed not only in the organizations to which he gave the best years of his life, but also by an almost unlimited number of friends and by the American College of Physicians.

—S MARX WHITE, M D, F A C P"

The Secretary-General then reported the following additional Life Members since the last meeting

Carl Herman Gellenthien, Valmoia, N M
Herman O Mosenthal, New York, N Y
Oiville H Brown, Phoenix, Ariz
Roy L Leak, Middletown, Conn

making a total of sixty-four Life Members

Dr James E Paullin, Chairman of the Committee on Public Relations, reported that his committee had examined into the correspondence and circumstances of the following resignations, which, by resolution of the Board of Regents, were accepted

Fellows

Dr Arthur F Cooper, Memphis, Tenn
Dr William J Young, Louisville, Ky

Associates

Colonel Glenn I Jones (Retired), M C, U S Army
Dr Ernest L Kiesel, Scranton, Pa

The Committee had received a communication from the late Dr James M Anderson (Master) concerning the establishment of a National Health Day. Since this topic of health education is already so well covered by local, state and public health organizations, the Committee merely recommended cooperation with these groups.

The Committee felt that an appeal from the American Association for China Famine and Flood Relief was without the purposes of the College, and recommended no action.

The Committee recommended that the facilities of the American College of Physicians be placed at the disposal of the Council on Medical Education of the American Medical Association for the promotion of residencies in internal medicine in approved hospitals, and that the College express itself as being in sympathy with attempts to develop better training in the field of internal medicine and its related specialties.

On motion by Dr O H Perry Pepper, seconded by Dr William D Stroud, and regularly carried, it was

Resolved, that the recommendations by the Committee on Public Relations be approved.

Reporting as a committee of one, Dr James H Means submitted the following suggested revision of the Fellowship Pledge, in accordance with a resolution adopted by the Board of Regents at one of its Detroit meetings

"Appreciating that the American College of Physicians has been created to foster the noblest principles and traditions of our calling, and having voluntarily accepted membership therein, I solemnly pledge that I will live in conformity with its ideals and regulations to the best of my ability.

"Especially do I dedicate myself to practice medicine following the Golden Rule and the good precepts of the Oath of Hippocrates, to place ever before my own, the welfare of patients dependent upon my professional knowledge and skill, to respect the interest and character of my colleagues, to supplement, as occasion requires, my own judgment with the wisdom and council of competent medical specialists, to render assistance willingly to my colleagues, to extend freely my professional aid to the unfortunate, the poor and the needy, to seek constant increase in medical knowledge through reading of authoritative literature and by attendance at important gatherings of my professional brethren, by study with physicians of eminence, and by free exchange of experience and opinion with my colleagues

"Further, I promise to refrain from seeking the public eye for purposes of self-advancement, to avoid commercialism in all my professional activities, to adjust my fees to the circumstances of my patients and to make them commensurate with the services I have rendered

"Moreover, I hereby condemn and promise to avoid all abasing money trades with brother practitioners or consultants, and I hereby swear that I will strive constantly to spread among all physicians with whom I come in contact a high ethic of practice like that set forth in the Constitution and By-Laws of the American College of Physicians"

Upon motion by Dr Means, seconded by Dr Barr, and regularly carried, it was *Resolved*, that the above Fellowship Pledge be approved in the place of the one heretofore used

Dr Maurice C Pincofs, as Editor of the ANNALS OF INTERNAL MEDICINE, presented a brief report upon the editorial work on the journal

Dr O H Perry Pepper, as Chairman of the House Committee of the College, reported that the new headquarters had been purchased for \$52,500, and after paying incidental expenses in connection with the transfer of title, settlement, etc, the Committee had a balance remaining of \$2,142.75 of the original appropriation for the purchase of the property at 4200 Pine Street, Philadelphia. Of the \$10,000.00 appropriated for alterations and furnishings, \$4,500 approximately had been spent on alterations, and \$4,500 approximately on furnishings, leaving a balance of \$929.16. There had been certain expenditures for taxes, additional insurance, etc, which had been charged against this appropriation, but which Dr Pepper felt should be charged to some other account, as a matter of bookkeeping. He described the alterations and furnishings that had been completed, and the proposed plan for future operation. In appreciation to Mr Charles J Eisenlohr, from whom the property was purchased, Dr Pepper moved the adoption of the following resolution, which was regularly seconded and unanimously carried

Resolved, that the Officers and Regents of the American College of Physicians extend to Mr Charles J Eisenlohr the thanks of the College for his many courtesies incident to the purchase from him of the new College Headquarters and also for his generous gift of various beautiful furnishings, including andirons, draperies, safe cabinet, billiard table, and other valuable items

Dr Sydney R Miller, Chairman of the Committee on Credentials, reported that of 91 names presented for Fellowship, either by promotion from Associateship or directly, 80 were recommended for election, 5 were recommended for election first as Associates, 3 were rejected, and 3 were deferred for further investigation. 186 names had been presented for Associateship, of which 152 were recommended for election, 21 were rejected, and 13 deferred. The names of those recommended for election, both to Fellowship and Associateship, were inspected by the Regents

Upon motion by Dr George Morris Piersol, seconded by Dr James E Paullin, and regularly carried, it was

Resolved, that the following list of 55 be and herewith are elected to Fellowship in the American College of Physicians as of this date, December 13, 1936

Dr Sydney R Miller then brought up the request of some Mexican candidates who had applied for the privilege of paying their initiation fee and dues in Mexican dollars, which are worth less than one-third of the equivalent in American currency. If the dues of Mexican members were accepted in Mexican dollars, the proceeds would be less than one-half the expenses of carrying such members on the Roster.

Upon motion by Dr O H Perry Pepper, seconded by Dr William D Stroud, and regularly carried, it was

Resolved, that members of the College in foreign countries, including Mexico, shall pay their fees and dues in American currency.

Dr David P Barr, Chairman of the Committee on Fellowships and Awards, reported that his Committee had found it desirable to choose the candidates for the Research Fellowship of the College at the autumn meeting of the Regents, rather than at the Annual Meeting. Seven excellent applicants had been given very careful consideration. The Committee recommended that the Research Fellowship for 1937-38 be awarded to Dr Robert Wallace Wilkens, now of Boston, Mass., for a year entirely devoted to research with Dr E Arnold Carmichael at the National Hospital, Queens Square, London, England.

Upon motion by Dr James Alex Miller, seconded by Dr William D Stroud, and regularly carried, it was

Resolved, that a Research Fellowship of the American College of Physicians, amounting to \$1,800.00 and available beginning July 1, 1937, be awarded to Dr Robert Wallace Wilkens.

The Committee on Fellowships and Awards further recommended that the John Phillips Memorial Award be given to Dr Richard E Shope of the Rockefeller Institute for Medical Research, Princeton, N J.

Upon motion by Dr David P Barr, seconded by Dr Jonathan C Meakins, and regularly carried, it was

Resolved, that the 1937 Award of the John Phillips Memorial Medal be made to Dr Richard E Shope.

Dr Barr reported that the Committee feels there is much room for profitable extension of the granting of Fellowships, and that this would afford one of the useful applications of the funds of the College.

Dr James H Means, Chairman of the Committee on the ANNALS OF INTERNAL MEDICINE, had no report to add to that already made by the Editor. He added, however, that the Committee would recommend to the Board of Regents that Dr Paul Clough be officially appointed Assistant Editor of the ANNALS.

Upon motion by Dr James H Means, seconded by Dr Robert A Cooke, it was *Resolved*, that the Board of Regents confirm the official appointment of Dr Paul Clough, of Baltimore, as Assistant Editor of the ANNALS OF INTERNAL MEDICINE.

Dr Jonathan C Meakins, Chairman of the Committee on Constitution and By-Laws, reported that his Committee had taken under consideration certain changes which should be recommended as amendments to the Constitution and By-Laws of the College.

PROPOSED AMENDMENTS TO THE CONSTITUTION

Article IV, "(a) Fellows. Fellows shall be members of the medical profession engaged as practitioners, teachers or research workers in Internal Medicine, who shall have been elected."

(change consists of the omission of "or in an allied specialty")

Article V, "Section 1. Associates shall be members of the medical profession engaged as practitioners, teachers or research workers in Internal Medicine, who shall have been elected."

(change consists of the omission of "or in an allied specialty")

On motion by Dr James Alex Miller, seconded by Dr William D Stroud, and regularly carried, it was

Resolved, that the Board of Regents approve of the amendments to the Constitution above outlined, and that notice of the proposal for these amendments shall be published in the *ANNAIS OF INTERNAL MEDICINE* in accordance with the requirements of the Constitution, Article VI

PROPOSED AMENDMENTS TO THE BY-LAWS

Article V, "Section 1 (a) He shall be more than 33 years of age,"

(change consists of a change in the age from 29 to 33)

"(c) He shall be a member in good standing in his local, state and national medical societies, except in the case of those not engaged in practice, such as full-time teachers or research workers in Internal Medicine,"

(change consists of elimination of "etc" and substituting "in Internal Medicine")

Article V, Section 2, line 6, eliminate "or by an Officer of the College, or by a member of the Board of Regents"

"Section 3 (a) In the case of practitioners without teaching or important hospital positions, or of candidates not engaged in the practice of Clinical Medicine, the candidate's nomination shall be accompanied by all necessary information as to fitness, by a satisfactory thesis, or by publications of sufficient number and character to qualify him for Fellowship"

(this is practically entirely reworded)

Note—In regard to outstanding persons in pathology, pharmacology, biochemistry, etc, these may be considered eligible under Article V, Section 3 (c), second paragraph, which should read as follows

"After 1931, a candidate for Fellowship shall be eligible only if already an Associate, except upon the high recommendation of the Committee on Credentials by reason of outstanding merit and accomplishment"

(this change consists of the rewording of the paragraph)

Article VI, "Section 1 He shall possess a Certificate from the American Board of Internal Medicine as having passed successfully the examinations of that Board"

(this is the insertion of an entirely new paragraph, entailing relettering the succeeding paragraphs—the present paragraph (a) becoming "(b)", (b) becoming "(c)", (c) becoming "(d)", (d) becoming "(e)", and (e) becoming "(f)")

Article VI, Section 1, old paragraph (c), new paragraph "(d) except in the case of those not engaged in practice, such as full-time teachers and research workers in Internal Medicine"

(this change consists of eliminating "those holding official hospital positions, etc" and substituting "in Internal Medicine")

Article VI, Section 1, old paragraph (d), new paragraph "(e)," line 6, "in Internal Medicine or in medical research"

(this change consists of the above substitution for "in one of the accepted branches of Internal Medicine or in Medical Research")

Speaking on the proposed changes to the By-Laws, Dr Meakins said the Committee had been faced with the problem of whether it should recommend changes requiring candidates to have passed successfully the examination of the American Board of Internal Medicine. There were three alternatives:

- (1) To make successful passage of the examination a prerequisite for Associateship,
- (2) To make successful passage of the examinations a prerequisite to Fellowship,
- (3) To ignore it altogether

The Committee felt that it would be better to make successful passage of the examinations a prerequisite to Associateship. This would assure the College that candidates for Associateship will have shown evidence of proper training, ethical standing, affiliations, etc., and would avoid the anomaly of admitting a candidate to Associateship who might later fail to pass the examination.

Upon motion by Dr James Alex Miller, seconded by Dr George Morris Piersol, and regularly carried, it was

Resolved, that the above proposed amendments to the By-Laws be submitted in writing to all members of the Board of Regents before its next meeting.

In the discussion of the proposed amendments to the By-Laws, there was divergence of opinion among Board members as to whether the requirement of certification by the American Board of Internal Medicine should precede Associateship, or be one of the requirements between Associateship and Fellowship. Several felt that Associates should be admitted much on the same plan as at present, with the exception of the amendment in the minimum age, but that before such an Associate may be eligible for Fellowship, he must obtain the certification of the American Board of Internal Medicine. By inserting this requirement between Associateship and Fellowship, the Committee on Credentials may eliminate the requirement of presenting case histories and autopsies, which have not proved a particularly satisfactory criterion in the past.

Dr Meakins, in discussing the underlying principles leading to the recommendation for amendments, in his report said, "In practically all the statements in the present Constitution and By-Laws, there is left considerable latitude as to research workers, laboratory workers, roentgenologists and the comprehensive term of an 'allied specialty'. A primary duty of the Credentials Committee is to review presented evidence, which would indicate that a candidate is sufficiently trained to practice Internal Medicine of a standard acceptable to the College. Whether, in the future, he should become engaged in hospital administration, medical research, roentgenology, etc., should not influence his future standing in the College. On the contrary, if his main activities have been for years in any of these branches of medical practice, no matter how high his reputation and accomplishments in these or other branches of medical practice, which are not directly concerned with the practice of Internal Medicine, they should not in any way justify his selection as an Associate of the College."

Dr Charles H Cocke, Chairman of the Board of Governors, inquired whether the Committee on Constitution and By-Laws had prepared any recommendation in regard to the appointment of alternate Governors.

Dr Meakins replied that his Committee had only considered the eligibility of candidates, but would take care of some provision for alternate Governors later on.

Dr Meakins asked for the opinion of the Board of Regents on a suggestion that there be created a group to be known as Emeritus Fellows, consisting of those who may retire, more or less, from the activities of the College on account of age.

During the discussion of the matter, the reaction seemed favorable, though no specific resolution was adopted.

Dr Walter L Biering, Chairman of the American Board of Internal Medicine, presented the following report

"The initiative for the formation of a certifying board for internists originated with the action of the American College of Physicians at the meeting of the Board of Regents in Philadelphia, April 30, 1935. At the meeting the Board of Regents voted to underwrite the organization expense of said Board up to the sum of \$10,000 00

"Concurrent action in the organization of the American Board of Internal Medicine was taken by the Section on the Practice of Medicine of the American Medical Association meeting in executive session at Atlantic City, June 14, 1935

"A joint Committee of Organization was formed comprising five representatives approved by President James Alex. Miller from the American College of Physicians, Meakins, Pepper, Barr, Richards, and Middleton, and four representatives, appointed by Chairman William J. Keir from the Section on the Practice of Medicine of the American Medical Association, Fitz, Irons, Musser and Biering, the latter was chosen as Chairman of the Joint Committee

"This Committee made its first report to the Board of Regents of the American College of Physicians at the meeting in Philadelphia, December 14, 1935, presenting a preliminary draft of the Constitution and By-Laws with an outline of the plan of examination and certification procedure

"The Articles of Incorporation of the American Board of Internal Medicine were filed for record on the 28th day of February, 1936

"At the meeting of the Board of Regents in Detroit, March 2, 1936, the organization of the American Board of Internal Medicine was officially approved and an appropriation of \$5,000 00 was voted to defray the expenses of the Board during the first year. At the meeting of the American Medical Association in Kansas City, May 12 and 13, 1936, the Board was given the final approval by the Section on the Practice of Medicine of the American Medical Association, the Advisory Board for Medical Specialties, and the Council on Medical Education and Hospitals of the American Medical Association

"With this final action, the American Board of Internal Medicine was duly organized and ready to begin operation

"The first meeting of the Board was held at the Palmer House, Chicago, June 14 and 15, 1936, at which the final details of organization were completed. The officers chosen for the first year were, Chairman, Walter L. Biering, Vice Chairman, Jonathan C. Meakins, Secretary-Treasurer, O. H. Perry Pepper, Assistant Secretary-Treasurer, P. M. Hutchinson, Attorney

"The terms of tenure of service of the members of the Board, as provided by the Articles of Incorporation, were determined by lot as follows

Representing the American College of Physicians

Dr Jonathan C. Meakins	1 year
Dr G. Gill Richards	1 year
Dr O. H. Perry Pepper	2 years
Dr William S. Middleton	2 years
Dr David P. Barr	3 years

Representing the Section on the Practice of Medicine of the American Medical Association

Dr Reginald Fitz	1 year
Dr Ernest E. Irons	2 years
Dr John H. Musser	3 years
Dr Walter L. Biering	3 years

"Attention is directed to Sections 5 and 7 of Article V of the Articles of Incorporation, which is as follows

"the membership of the Board shall be maintained at the ratio of five members from the American College of Physicians and four members from the Section on the Practice of Medicine of the American Medical Association and that at least three of the members of the Board from the American College of Physicians and two members of the Board from the Section on the Practice of Medicine of the American Medical Association shall be of professorial rank in approved medical schools of the United States or Canada"

Section 5, Article V, Articles of Incorporation

"The term of office of members of the Board succeeding the original Board members shall be three years and until their successors are elected and qualified, and no such member shall serve more than two consecutive three-year terms"

Section 7, Article V, Articles of Incorporation

"The following committees were named

Credentials and Qualifications

Dr Jonathan C Meakins, *Chairman*
 Dr William S Middleton
 Dr Ernest E Irons
 Dr Reginald Fitz

Examinations

Dr David P Barr, *Chairman*
 Dr O H Perry Pepper
 Dr G Gill Richards
 Dr John H Musser

"It was further decided at this meeting that the central office of the Board be maintained, for the present, at the office of the Chairman at 406 Sixth Avenue, Des Moines, Iowa

"During the months of July and August, 1936, in accordance with the directions of the Board, a publicity statement regarding the American Board of Internal Medicine, presenting its object and purposes with an outline of the special training and method of examination required of candidates for certification was released to 75 different medical journals, including the Annals of Internal Medicine, Journal of the American Medical Association, Canadian Medical Association Journal, British Medical Journal, all State Medical Society Journals, and special journals. The statement was published complete or in abstract in practically all of the Journals submitted, and quite a number added favorable editorial comment

"More complete information regarding the Board was later published in the form of a handbook

"The second meeting of the Board was held in Chicago, October 11 and 12, 1936, at which time the date for the first written examination was set for Monday, December 14, 1936, in different cities throughout the United States, and wherever possible, to be at or near the place where the applicant resides. The written examination shall consist of two parts

A A three-hour examination upon subjects in anatomy, physiology, pharmacology, pathology, biochemistry, bacteriology, and immunology, which are related to the proper understanding of Internal Medicine. This shall be held at 9 00 o'clock, a m., on the day of the examination

B A three-hour clinical examination of a general character to be held at 2 00 o'clock, p m, on the day of the examination

"The fees for examination have been set as follows

For Written and Practical Examination	\$40 00
For Certificate	10 00
For Certification without Examination	10 00

"At this meeting the following amendment to Article VI of the By-Laws, pertaining to special certification, was adopted

"To amend Article VI by striking out all of Article VI and substituting the following

ARTICLE VI

Special Certification

Advisors to the Board

Section 1 A There shall be appointed to the Board a group of leading internists, not to exceed two hundred and fifty (250) in number, who shall be known as Advisors to the Board They shall be certified without examination and their duties shall be to assist and advise the Board in the selection of Founders, the holding of examinations and such other duties as the Board may require of them

B They shall be selected by the Board as the Board may decide

Founders

Section 2 Until July 1, 1937, certificates of the American Board of Internal Medicine will be issued without examination to a limited number of specialists in Internal Medicine approved by the Board from the following

A Professors and associate professors of medicine in approved schools of medicine of the United States and Canada

B Physicians who have practiced the specialty of Internal Medicine for ten years, and are members or Fellows in good standing in one or more of the following special societies of internal medicine

- 1 American College of Physicians
- 2 Royal College of Physicians of Canada
- 3 Association of American Physicians
- 4 American Clinical and Climatological Association
- 5 American Gastro-enterological Association
- 6 American Society for Clinical Investigation
- 7 Central Society for Clinical Research

C Physicians who have practiced the specialty of Internal Medicine for fifteen years, and who are recommended by the Executive Committee of the Section on the Practice of Medicine of the American Medical Association

"It was moved that the Advisors to the Board be selected from the following

- 1 Professorial heads of departments of Internal Medicine of all the approved medical schools of the United States and Canada No such individual shall be eligible who is not an internist
- 2 Emeritus and active members of the Association of American Physicians who are internists

- 3 The officers and members of the Board of Regents for the year 1936-37 of the American College of Physicians who are internists
- 4 The Advisors to the Board must be 45 years of age or over, except those chosen under paragraph No 1 above
The Advisors to the Board shall be certified without examination upon the payment of the regular certification fee of \$10 00
- 5 An original member of the American Board of Internal Medicine shall, ipso facto, be certified without examination On termination of his membership on the Board he shall automatically become an Advisor to the Board

"It was the opinion of the Board that the Founders should be selected from applications addressed to the Board rather than from invitations sent out by the Board from a prepared list It was decided that the following letter be sent to prospective Founders

"The American Board of Internal Medicine, organized through the cooperation of the American College of Physicians and the Section on the Practice of Medicine of the American Medical Association, may issue a certificate of qualification without examination to a limited number of specialists, according to Section 2, Article VI of its By-Laws as follows

Section 2 Until July 1, 1937, certificates of the American Board of Internal Medicine will be issued without examination to a limited number of specialists in Internal Medicine, approved by this Board from the following

- A Professors and Associate Professors of Internal Medicine in approved schools of medicine of the United States and Canada
- B Physicians who have practiced the specialty of Internal Medicine for ten years, and are members or Fellows in good standing in one or more of the following special societies of Internal Medicine

- 1 American College of Physicians
- 2 Royal College of Physicians of Canada
- 3 Association of American Physicians
- 4 American Clinical and Climatological Association
- 5 American Gastro-enterological Association
- 6 American Society for Clinical Investigation
- 7 Central Society for Clinical Research

- C Physicians who have practiced the specialty of Internal Medicine for fifteen years, and who are recommended by the Executive Committee of the Section on the Practice of Medicine of the American Medical Association

"As all others must pass an examination it seems but reasonable to the Board that those who are admitted without examination should show evidence of qualifications equivalent, or better, to that which the Board requires of those who apply for admission through examination

"The Board will give consideration to those who graduated or took their internship prior to the date of the establishment of the present standards of the Council on Medical Education and Hospitals of the American Medical Association

"If you are desirous of submitting your name you are requested to fill out the enclosed form and return to the office of the Chairman in the enclosed envelope

for consideration by the Board as to your eligibility for certification without examination

" 'A registration fee of \$10 00 must accompany this application ' "

"In conformity with the action of the Board at its last meeting on October 11-12, 1936, the list of Advisors to the Board was completed as selected from the following, in accordance with the method previously stated

- 1 Professorial heads of departments of Internal Medicine of all approved medical schools of the United States and Canada
- 2 Emeritus and active members of the Association of American Physicians
- 3 Officers and members of the Board of Regents for the year 1936-37 of the American College of Physicians who are internists

All Advisors to be 45 years of age or over, except those chosen as professorial heads of departments of Internal Medicine

This list comprised 188 names. An individually signed letter was sent to each Advisor selected of the form adopted at the last meeting. The response was very gratifying as 168 favorable replies were received, each expressing interest in the purpose of the Board and appreciation for the selection. Eight of the Advisors selected had retired from active practice and preferred not to serve. Of the remaining 160, all but 6 have remitted the registration fee of Ten Dollars "

(Dr Bierring at this point presented the list of Advisors)

"The selection of a Founders list has not progressed as rapidly. Letters of the form adopted at the last meeting have been mailed to 1,500 Fellows of the American College of Physicians during the past week. Each letter was signed personally by the Chairman and an application enclosed for certification without examination, a statement of qualifications required of candidates taking the examination, and a business return envelope

"Letters are now being prepared for members and Fellows of the following societies, who are not Fellows of the American College of Physicians or Advisors of the Board

- 1 Royal College of Physicians of Canada
- 2 Association of American Physicians
- 3 American Clinical and Climatological Association
- 4 American Gastro-enterological Association
- 5 American Society for Clinical Investigation
- 6 Central Society for Clinical Research

"In addition, the professorial heads of Internal Medicine, who are Advisors, have been asked to submit a corrected list of professors and associate professors of Internal Medicine in their respective schools, and answers have been received from all, with a few exceptions

"The entire list of Founders to be considered will probably comprise 2,500 names

"The preparations for the first written examination on December 14, have proceeded in accordance with the plans adopted by the Board at the last meeting. Advisors of the Board have been assigned to serve as supervisors of the examination in the different cities with two exceptions—Bismarck, N D, and Orlando, Fla. (In Bismarck, N D, the State Health Officer, Dr Maysil Williams will act as supervisor, and in Orlando, Fla, Dr Meredith Mallory, F A C P, will act in a similar capacity)

"In each instance the candidate has been assigned a registration number, which will be retained throughout all the examinations, and directed by telegram to report at the designated place of examination on Monday, December 14, 1936, at 9 00 o'clock, a. m. A copy of this telegram is sent to the supervisor concerned for purposes of identification.

"A set of examination questions of Part 1 and Part 2 has been sent to each supervisor in separately sealed envelopes by special delivery mail. A supply of blank examination paper arranged in booklets has also been sent to each supervisor.

"The directions for conducting the written examination as submitted to each supervisor are as follows:

"The examination will be in charge of the Advisor selected by the Board, who will observe the following directions and regulations:

- 1 Hold the examination on the day and hour prescribed
- 2 Admit to the examination only those candidates who hold letter of admission from the Board
- 3 Ascertain that the identification number given by each candidate, which is to be used on all of the answer papers, corresponds with the number assigned by the Board
- 4 Break the seal of the question papers in the presence of the candidate at the beginning of each session of the examination
- 5 Collect the answer papers after each session and at the close of the examination period, enclose these with identification forms, unused examination paper and questions, in addressed envelopes, and forward by express, collect, to the office of the Chairman, Room 1210, 406 Sixth Avenue, Des Moines, Iowa, U S A."

(Dr. Bierring stated at this point that there had been 53 candidates approved for admission to the first written examination, and gave the assignment of candidates with respect to the cities and examiners throughout the United States.)

"The Committee on Credentials and Qualifications did not approve eight applicants, because of insufficient qualifications. Each of the applicants was refunded \$30 00 of the examination fee, \$10 00 being retained as the registration fee.

"Four applicants having paid the examination fee of \$40 00, upon further review by the Committee were recommended for certification without examination, and a refund will be made of \$30 00 each. Three applications submitted for certification without examination, previously considered by the Board and resubmitted to the Committee on Credentials and Qualifications, were subsequently recommended for reference to the Executive Committee of the Section on the Practice of Medicine of the American Medical Association for further action. These have been forwarded as directed, but to date have not been returned.

"Four applications have been received to date for the second written examination to be held during March, 1937.

"The amount received by the Chairman for registration and examination fees, to date, is \$4,310 15, of which \$250 00 has been refunded, leaving a balance of \$4,060 15 deposited in the Bankers Trust Company Bank, Des Moines, Iowa, to the account of the American Board of Internal Medicine, Walter L. Bierring, Chairman. It is to be noted that fees collected are to a certain extent a liability held in escrow until all examinations and certification procedure have been completed.

"All current expenses of the Board are paid out of the allotment of \$5,000 00 granted by the American College of Physicians. Up to and including November 30, \$3,761 12 has been expended. The estimated expense of this meeting and of current

expenses to and including December 31, 1936, is \$875 00, making a total of \$4,636 12, leaving an approximate balance January 1, 1937, of \$363 88

"In view of the increasing volume of work connected with the present operation of the Board and two meetings in prospect, April and June, 1937, it is estimated that at least \$3,000 00 will be required to carry on until July 1, 1937. By this date it is reasonable to anticipate a considerable fund will be available from fees retainable

"At the meeting of the American Board of Internal Medicine on December 12, 1936, the Chairman was directed, on behalf of the Board, to make application to the Board of Regents of the American College of Physicians for an additional grant of \$3,000 00 to be available to June 30, 1937, it being understood that this grant of \$3,000 00 in addition to the former grant of \$5,000 00 is to be considered as a loan to the American Board of Internal Medicine to be refunded as soon as definite funds are available"

In conclusion, Dr Bierring, on behalf of the American Board of Internal Medicine, thanked the Board of Regents for the wise counsel and financial aid which had been extended

On motion by Dr James Alex Miller, seconded by Dr James E Paullin, and regularly carried, it was

Resolved, that the Board of Regents of the American College of Physicians express their appreciation of the progress that has been made by the American Board of Internal Medicine, and that the College approve the appropriation of the further amount of \$3,000 00

Dr William D Stroud submitted the following report, as Treasurer

"Investments in Bonds, approximately	\$80,000 00
Investments in Preferred Stocks	4,427 00
Investments in Common Stocks	15,500 00
Uninvested Cash in Endowment Fund	527 00
Cash in General Fund	27,977 00

"About \$1,500 00 had been received from closed banks in Pittsburgh on account during the past year

"The total assets, including investments, cash and the College Headquarters, approximate \$183,000 00"

On motion by Dr James Alex Miller, seconded by Dr James E Paullin, and regularly carried, it was

Resolved, that the report of the Treasurer be accepted and filed. Dr James Alex Miller made a detailed report for the Finance Committee

"The analysis of the Girard Trust Company of our securities was considered, and it was voted to approve the recommendations of their report

"It was voted to withdraw our savings account and to invest it at some such good time in income bearing securities, after receiving recommendations from the Girard Trust Company, which would be circulated to the members of the Finance Committee

"It was recommended that the Board of Regents approve the expenditures for taxes and insurance on the new headquarters as an item of upkeep, amounting to \$1,109 63, which temporarily had been drawn from the funds appropriated for purchase and furnishings

"It was recommended that the Board of Regents set up a repair and replacement fund, which it was suggested should amount to \$500 00 a year

"We would report that according to the estimate of the upkeep for 1937 in the new headquarters, the upkeep expenses will be \$3,480 00, and that the capital outlay, \$62,000 00 at 4 per cent interest, would be \$2,480 00, so that the total upkeep and rental for the new headquarters would be approximately \$6,000 00 a year

"The Finance Committee considered in detail the 1937 budget presented by Mr E R Loveland in behalf of various departments, and recommends it for approval

by the Regents as submitted, with estimated receipts of \$77,500 00 and estimated expenditures of \$60,257 67, an estimated balance of \$17,242 33

Respectfully submitted,

JAMES ALEX MILLER, *Chairman,*
Committee on Finance"

Upon motion by Dr Francis M Pottenger, seconded by Dr William Gerry Morgan, and regularly carried, it was

Resolved, that the report of the Finance Committee be approved, and the Committee authorized to make the sales and purchases recommended, further that the Treasurer be authorized to withdraw the funds from the savings accounts, and to invest the funds in securities to be approved by the Finance Committee, further that the Board of Regents approve the expenditures for taxes, insurance, etc, on the new headquarters, amounting to \$1,109 63, and that this appropriation be added to the original appropriations for 1936, further that the Board of Regents approve the setting up of a repair and replacement fund of \$500 00 per year—this amount merely being set aside if needed, but not otherwise withdrawn from invested funds, further that the detailed budgets recommended by the Finance Committee for 1937, with estimated receipts of \$77,500 00 and estimated expenditures of \$60,257 67, be approved

Dr Ernest B Bradley, President, outlined the plans for the St Louis Session, April 19-23, 1937, so far as the General Program and Convocation were concerned Dr David P Barr, General Chairman, discussed the tentative program for the clinics, and Mr Loveland, Executive Secretary, reported upon the business arrangements Almost all the available exhibit space has been disposed of and all details have been arranged with the headquarters' hotel, the New Jefferson

Dr James Alex Miller, Chairman, presented a report of progress for the Committee on Future Policy for the Development of Internal Medicine This Committee had considered the comparative value of the John Phillips Memorial Award, the advisability of inviting speakers and lecturers from abroad and from the United States to give lectures under the auspices of the College and at its expense, and the idea of establishing a revolving fund to help younger practitioners to meet the requirements for registration as internists The Committee had also considered the possibility of maintaining a directory of postgraduate activities to be published in the *ANNALS*

No action had been taken on any of these suggestions

Dr James Alex Miller also brought up the situation concerning the National Conference on Nomenclature of Disease He stated that the Conference had published a Nomenclature of Disease which is now widely used, and which meets with wide approval Through some oversight, an invitation to the College to participate in this work had not been accepted by the College in the year 1929 On behalf of the Chairman of the Executive Committee of the National Conference, Dr Miller renewed the invitation to the College to cooperate with the long list of associations comprising the Conference

Dr Miller moved that the College lend its name in cooperation to the National Conference on Nomenclature of Disease

This was seconded by Dr William D Stroud, and regularly carried

On motion by Dr George Morris Piersol, seconded by Dr Walter L Bierring, and regularly carried, it was

Resolved, that the College make an appropriation of \$1,000 00 for the aid of this worthy work

On motion by Dr William D Stroud, seconded by Dr Sydney R Miller, it was moved that the American College of Physicians establish another Research Fellowship of \$1,800 00 for one year, July, 1937, to June, 1938

In the discussion of the motion, it was agreed that the action was not to establish two Fellowships permanently, that in some years there might be more and in other years possibly none The motion was carried

On the recommendation of Dr David P Barr, on behalf of the Committee on Fellowships and Awards, by a motion made, seconded and regularly carried, it was

Resolved, that this Fellowship be awarded to Dr Abner McGhee Harvey, now of the Johns Hopkins Hospital, Baltimore, Md

In the absence of Dr James D Bruce, Chairman, Dr Jonathan C Meakins reported for the Committee on College Records of Members The Committee, utilizing the form now in use in connection with the publication of the annual Directory, suggested an appropriate form which by resolution was adopted

Dr James Alex Miller, on behalf of Dr Walter W Palmer, Governor for eastern New York, Dr Luther F Warren, Regent, Dr Robert A Cooke, Regent, and himself as Regent, presented the following invitation for the 1938 Annual Session of the College to be held in New York City

"We, the officers of the American College of Physicians, who reside in New York City, desire to request the favorable consideration of the Board of Regents of an invitation to hold the meeting of the College in 1938 in New York City

"Preliminary inquiries have established the fact that we would be able to obtain suitable hotel and auditorium facilities here and also that we would have the whole-hearted cooperation of the large medical centers for the presentation of the clinical programme

"The situation in New York is not one that lends itself to the usual method of presentation of an invitation for a meeting of the College, that is, it is not customary for organizations such as the County Medical Society, the Academy of Medicine or individual hospitals to invite medical organizations to meet in New York City Consequently, we are asking you to consider this invitation as representing the hearty feeling of the Fellows of the College in New York City and of the principal hospital and educational institutions which would participate in the meeting

Very respectfully yours,

(Signed) WALTER W PALMER, *Governor*

(Signed) LUTHER F WARREN, *Regent*

(Signed) JAMES ALEX MILLER, *Regent*

(Signed) ROBERT A COOKE, *Regent*"

Upon motion by Dr James H Means, seconded by Dr Robert A Cooke, and regularly carried, it was

Resolved, that members of the Board of Regents shall tender a Dinner to members of the Board of Governors at the St Louis Session, as was done at the last Annual Session in Detroit

President Bradley inquired if there was any desire to change the ruling with regard to any allowances for traveling expenses of the Regents for the Annual Sessions There was a consensus of opinion that this should stand as at present, namely, their return convention and pullman fare, without any allowance whatsoever for hotel or other expenses

Adjournment

Attest (signed) E R LOVELAND,
Executive Secretary

OBITUARIES

DR HENRY S PLUMMER

DR HENRY S PLUMMER was born in Hamilton, Minnesota, on March 3, 1874, the son of Dr Albert Plummer and Isabelle Plummer. He died in Rochester, Minnesota, on December 31, 1936, of cerebral thrombosis. His early education was obtained in the local public schools and in the University of Minnesota. He attended the Medical School of Northwestern University, from which he received the degree of Doctor of Medicine in 1898. His first three years of practice were spent with his father in Racine, Minnesota, and in 1901 he entered The Mayo Clinic, where he continued the practice of medicine until his death.

In the early years of his practice he became deeply interested in roentgenology, bronchoscopy and esophagoscopy. His early work in the treatment of cardiospasm and esophageal stricture resulted in an important contribution to medicine, and his hydrostatic dilator and esophageal sounds, first designed and made by him in his own workshop, are still in use in the treatment of those conditions. Throughout his years of medical practice his greatest interest was in the function and diseases of the thyroid gland. Early in his experience, his keen clinical observations allowed him to define the two entities, exophthalmic goiter and hyperfunctioning adenomatous goiter. His development of a "two-product hypothesis" in exophthalmic goiter led, in 1921-22, to the demonstration of the beneficial effect of the administration of iodine to patients with exophthalmic goiter. This, his most outstanding contribution, has been responsible for a marked and general lowering in the mortality of exophthalmic goiter. His opinions on diseases of the thyroid are accepted as authoritative both in this country and abroad. His contributions to the literature were prepared with meticulous care, and were always the result of exhaustive study. He was apt, however, to leave unpublished a great deal that he knew and understood. It was this propensity that enabled him to teach his associates more by intimate contact and direction than by what he put into the literature.

Dr Plummer's interests were, however, not limited to medicine. Whatever he became interested in he studied in the greatest detail. He gave much thought to the improvement of facilities for the care of patients, and the utilitarian features of the design of The Mayo Clinic building came largely from his mind. His opinions were sought on a variety of subjects, among them horticulture, building construction, and engineering.

Dr Plummer was elected a Fellow of the American College of Physicians March 11, 1922, and served as a Regent of the College from 1923 to 1927. He was also a Fellow of the American Medical Association. He held membership in the Association of American Physicians, Association for the Study of Internal Secretions, American Association for the Advance-

ment of Science, American Association for the Study of Goiter, American Gastro-Enterological Association, Medical Library Association, American Association for Thoracic Surgery, American Public Health Association, Royal Society of Arts, Minnesota Pathological Society, Southern Minnesota Medical Association, Central Interurban Clinical Club, Minnesota Society of Internal Medicine, Central Society for Clinical Research, Minnesota State Medical Association, Olmsted-Houston-Fillmore-Dodge County Medical Society, Alumni Association of The Mayo Foundation, Sigma Xi, Alpha Omega Alpha, Minnesota Horticultural Society, University Club of Rochester, and St Paul Athletic Club

In 1920-21 he was the chairman of the Section on Practice of Medicine of the Scientific Assembly of the American Medical Association. In 1933 he was elected President of the American Association for the Study of Goiter, and in 1935 Northwestern University conferred on him the degree of D Sc (honoris causa). Since 1915 he had been Professor of Medicine, The Mayo Foundation, Graduate School, University of Minnesota.

Dr Plummer was a keen observer and had a remarkable ability to correlate the masses of facts which he accumulated. He had great knowledge of human problems, and his philosophy of medicine was tempered by a wide humanitarian outlook. His sense of fairness was outstanding. In him were combined to a remarkable degree the finest characteristics of clinician and investigator. His life was devoted to a constant and unusually productive effort to improve the quality of the care of the sick. By his death Medicine has lost a prodigious worker and a great physician, and his associates have lost a friend, a guide, and an inspiration.

SAMUEL F. HAINES, M.D., F.A.C.P.

DR. JAMES ALLISON HODGES

JAMES ALLISON HODGES died on December 15, 1936, at the age of 78. Born in North Carolina, his early education was obtained at preparatory schools and at Davidson College in that State; in 1883 he was graduated from the department of medicine of the University of Virginia. After practicing several years in Fayetteville and Wilmington, N. C., he moved in 1893 to Richmond and became affiliated with the newly organized University College of Medicine as Professor of Anatomy. In 1896 he became Professor of Nervous and Mental Diseases and for a time served as President of that institution. Upon the merging of the University College of Medicine with the Medical College of Virginia in 1914 he became Professor of Clinical Neurology and Psychiatry in the latter, a position he held up to 1927, when he became Professor Emeritus. In addition to an extensive practice and teaching, he operated the Hygeia Hospital, a private institution, from 1903 to 1920, and for a number of years was medical director of a large life insurance company.

Dr Hodges took an active and prominent part in a number of medical organizations. He was one of the founders in 1897 of the Tri-State Association of Virginia and the Carolinas, and in 1918 its President. In 1923 he served as President of the Richmond Academy of Medicine. In the Medical Society of Virginia he was always active, serving as President in 1930 and contributing regularly toward its welfare and advancement. In 1916 he became a Fellow of the infant American College of Physicians and might be considered one of its charter members.

A man of imposing presence, tremendous energy and great ability, Dr Hodges was always ready to assist in any undertaking designed for the advancement of medicine or the betterment of society. A gifted speaker, his services were in much demand and numerous worthy causes profited from his efforts.

Following a coronary thrombosis a few years ago, Dr Hodges' activities have been greatly restricted, but he continued up to the time of his death in full possession of his faculties and manifested a lively interest in contemporary affairs, both professional and civic.

J MORRISON HUTCHESON, M D , F A C P ,
Governor for Virginia

DR ERNEST E LAUBAUGH

DR ERNEST E LAUBAUGH, Fellow and Governor of the American College of Physicians for the State of Idaho, died, December 13, 1936, after a four-day illness from influenza-pneumonia, at the age of forty-nine years.

Dr Laubaugh was born at Shickshinny, Pennsylvania, August 20, 1887. He attended the public schools of Philadelphia and received his medical degree from the Medico-Chirurgical College of Philadelphia in 1909. He interned at the Mercy Hospital, Wilkes-Barre, Pennsylvania, 1909, and the Philadelphia General Hospital, 1910-11. He continued with this institution as Scrologist during 1912-13. During 1911-12, he was Assistant Demonstrator in Physical Diagnosis, and during 1912-13, Assistant in the Department of Neurology of the Medico-Chirurgical College. In 1913, he accepted an appointment as Bacteriologist on the Idaho State Board of Health, which appointment he held until 1917. During 1919-20, he was Medical Advisor to the Department of Public Health of Idaho. From 1919-23, he was Consultant to the U S Veterans Hospital in Boise. At the time of his death he was a member of the staff of the St Alphonsus and St Luke's Hospitals in Boise.

During the World War, he was a first lieutenant in the U S Army, later advancing to a captaincy, and was stationed at the Port of Embarkation, Newport News, Virginia.

Dr Laubaugh was a member of the Omega Upsilon Phi fraternity, Boise Physicians Club, Idaho State Medical Association, Southwestern Medical Society of Idaho, American Society of Bacteriologists, American

Heart Association, he was a Fellow of the American Medical Association, the American Society of Clinical Pathologists, and had been a Fellow of the American College of Physicians since 1927

He made a number of contributions to medical literature and had held a distinctly outstanding position as an internist in Idaho and the northwest. He was a member of the Episcopal Church, American Legion and the Masonic fraternity. He is survived by his widow, Mrs Beth Laubaugh, a son, James E Laubaugh and a daughter, Lucile Laubaugh.

Those who knew him remember him as a quiet, genial, kindly and earnest physician, unassuming in manner, yet determined to keep abreast of the latest developments in his specialty and to give his patients always the benefits of his skill and care. Many Fellows of the College who took the official cruise to Cuba and Panama, following the last New Orleans Session of the College, will more vividly remember Dr Laubaugh as one of the party. He had been a Governor of the College for the State of Idaho since 1928, and had served the College with the same efficiency, earnestness and integrity as he practiced his profession.

E R LOVELAND,
Executive Secretary

DR WILLIAM FREDERICK WEGGE

WILLIAM FREDERICK WEGGE (Fellow), Milwaukee, Wisconsin, died on November 20, 1936, at the age of seventy-three.

Dr Wegge, a native of Wisconsin, first studied dentistry at Baltimore University. After practicing that profession for a few years he returned to the University of Maryland School of Medicine, from which he was graduated in 1886. He took several post-graduate courses in Austria and Germany, specializing in mental disorders. Upon his return from Europe he did general practice for a short time and then held the position of Superintendent at the Northern Hospital for the Insane at Winnebago. Following his service at the State Hospital he located in Milwaukee, limiting his practice to neuropsychiatry. He was for many years Professor of Neuropsychiatry at the Milwaukee Medical College, and at the time of his death was Emeritus Director of the Division, and Professor of Clinical Neurology, Marquette University School of Medicine. He was a member of the Medical Society of Milwaukee County, the State Medical Society of Wisconsin, the American Medical Association, and Past-President of the Milwaukee Neuropsychiatric Society. He was elected a Fellow of the American College of Physicians in 1930.

CIRCULATORY STUDIES ON ANOXEMIA IN MAN WITH RESPECT TO POSTURE AND CARBON DIOXIDE¹

By E. GELLHORN, M.D., Ph.D., *Chicago, Illinois*

Mosso,²² Margaria,²⁰ Childs, Hamlin and Henderson⁴ noted that the effects of anoxemia can be alleviated by breathing low concentrations of CO₂. In several studies (Gellhorn^{7,8}) we have confirmed and extended these observations on a quantitative basis. It was shown in particular that the effects of anoxemia on various processes occurring in the human central nervous system can be offset by inhaling 3 per cent CO₂ during the period of anoxemia. This effect was thought to be due mainly to circulatory and respiratory adjustments. This idea is supported by the fact that under the influence of CO₂ the circulation through the brain is specifically increased (Cobb and Fremont-Smith,⁹ Lennox and Gibbs,¹⁰ Gibbs, Gibbs and Lennox,¹² and Schmidt²⁴). Furthermore, due to increased muscle tonus, there is an improvement in general circulation indicated by a rise in venous pressure (Henderson and collaborators¹¹). Other factors will be discussed below.

The present investigation was undertaken with the aim of establishing, in the human, direct proof for the improvement of the general circulation by CO₂ under the conditions of oxygen deficiency. Since the circulation in the brain, in which the symptoms of oxygen deficiency become first manifest, is primarily dependent on the systemic blood pressure, comparative blood pressure studies on the effect of oxygen deficiency with and without the simultaneous administration of CO₂ seemed appropriate. The fact that under ordinary circumstances oxygen want causes only very slight changes in the systemic blood pressure (Raab,²³ Gellhorn and Spiesman,^{9,10} Christensen and Krogh,⁵ and Herbst and Manigold¹⁶) does not invalidate this argument. In order to show the influence of one particular factor on the blood pressure which is normally maintained by the integrative action of several peripheral and central nervous factors and by the O₂—and CO₂—tension of the blood,

* Received for publication November 30, 1936

From the Department of Physiology, College of Medicine, University of Illinois

it seemed appropriate to study the circulatory system under a certain strain which might make the whole system more labile. If such a condition were found it was not improbable that the beneficial effect of CO_2 , which was so distinct in our investigations on various functions of the central nervous system under the influence of oxygen want, would also become evident in regard to blood pressure.

As we now know, the maintenance of the blood pressure is dependent to a large extent on the functioning of carotid sinus and depressor reflexes (Hering,¹⁶ Koch,¹⁸ Heymans¹⁷). When the pressure falls in the aorta and in the carotid artery these reflexes are evoked and the normal blood pressure is restored. Therefore changes in posture are ordinarily not accompanied by significant changes in systemic blood pressure. Under conditions of oxygen want, however, the blood pressure falls considerably in the erect posture, whereas the same degree of oxygen want does not significantly alter the blood pressure in a recumbent position (Mateeff and Schwarz²¹). For this reason the effect of CO_2 under conditions of oxygen deficiency was studied on humans in the erect posture.

METHOD

The pulse was counted at one minute intervals and blood pressure readings, systolic and diastolic, were taken by two experimenters while the experimental subject was standing and inhaling a gas mixture from a Douglas bag. The gas mixture was prepared with the aid of a Sargent gas meter and frequently analyzed for O_2 and CO_2 . The duration of the experiment was seven to twelve minutes. It was preceded and followed by a control period in which the experimental subject inhaled air. The shift from air to the gas mixture and from that back to air was performed without the knowledge of the experimental subjects. The subjective and objective symptoms observed during the experiments were protocolled immediately after the experiments. The observations were made on 12 healthy experimental subjects, medical students of the ages of 20 to 25, most of whom had served as experimental subjects in experiments in which the effect of O_2 deficiency was studied in regard to various functions of the central nervous system. In some cases the experiments were repeated several times on the same subject without any essential difference in the results.

RESULTS

Figures 1a and 1b show the effect of 8.5 per cent O_2 , and 8.5 per cent O_2 plus 3 per cent CO_2 , respectively, on pulse and blood pressure during a period of nine to ten minutes. In the 8.5 per cent O_2 experiment the systolic blood pressure rises by 10 to 14 mm. mercury during the first three minutes, and then falls gradually below the control value. At the same time the pulse rate which had risen considerably also shows a drop, which even continues for a short time after the readmission of air. The diastolic

blood pressure shows only a slight decrease. All changes were nearly completely reversed in the first five minutes following the period of O_2 want. The characteristic feature of this and similar experiments is the fact that the increase in blood pressure and pulse rate resulting from anoxemia does not persist throughout the experiment but that a collapse-like reaction occurs

1a

1b

FIG 1a and 1b 85 per cent O_2 and 85 per cent O_2 plus 3 per cent CO_2 respectively between arrows (Subject He, erect posture) (Figs 1-4 and 6-7 — systolic blood pressure, ---- diastolic blood pressure, pulse rate per min. Abscissa time in min, ordinate blood pressure in mm Hg and pulse rate per min.)

characterized by a more or less abrupt decrease in systolic blood pressure and pulse rate, accompanied by considerable weakening of the pulse, pallor and dizziness. In some experiments showing the same type of reaction a sudden collapse sets in and the pulse becomes imperceptible but the recovery is fast.

Comparing with this experiment the results obtained from the same subject under the conditions of the same degree of oxygen want, but in the presence of 3 per cent CO_2 , we see an enormous contrast (figure 1b). The systolic blood pressure is slightly elevated and remains so throughout the whole period of O_2 want. The changes in pulse rate are slight, but the increase observed also persists until air is readmitted. The diastolic blood

FIG 2a and 2b 85 per cent O_2 and 85 per cent O_2 plus 3 per cent CO_2 respectively between arrows (Subject Fa, erect posture)

pressure shows an increase during the experiment. The subjective experiences of the subject are equally striking. In general the subjects feel fairly well except for a slight dizziness or feeling of warmth. In some cases no symptoms whatever are observed, even though certain of these cases had experienced severe symptoms in the absence of 3 per cent CO_2 .

Figure 2 represents the record of an experiment in which the circulatory adjustment under oxygen want is still poorer than in the first case (figure 1)

After admission of 8.5 per cent O_2 in erect position the systolic blood pressure gradually falls and remains fairly low during the period of anoxemia. The pulse rate shows irregular variations without any definite tendency. The diastolic blood pressure is practically unaltered. In contrast to this reaction we observe, in the corresponding oxygen deficiency experiment in which 3 per cent CO_2 was also administered, that the fall in blood pressure is

FIG 3a and 3b 8.5 per cent O_2 and 8.5 per cent O_2 plus 3 per cent CO_2 respectively between arrows (Subject St, erect posture)

not only completely prevented but that the blood pressure remains elevated throughout the experimental period. Furthermore, a distinct increase in pulse rate occurs during this time.

A very similar type to that shown in figure 2 is illustrated in figure 3. The main difference between the two experimental subjects is the fact that the systolic blood pressure is considerably higher to begin with in the case

of subject S (figure 3) than in that of F (figure 2). It is striking to see that the systolic blood pressure falls continuously until it reaches a certain equilibrium and that permanent changes in pulse rate are absent in anoxemia, whereas in the presence of 3 per cent CO_2 a marked increase in pulse rate occurs and the fall in systolic blood pressure is completely prevented. The difference in the two subjects whose curves are illustrated in figures 2 and 3 is, as was mentioned, a difference in the absolute values for the systolic pressure. This seems to be of considerable importance. S, whose systolic blood pressure is considerably greater than that of F, shows far less symptoms than the latter, obviously for the reason that the circulation of the brain can be maintained to a better degree in the first case than in the second,

FIG 4 8 per cent O_2 between arrows (Subject G, erect posture)

since, as it is well known, the degree of circulation through the brain is largely dependent on the level of the systemic blood pressure (Starling²⁶). The experiments discussed so far have one feature in common, namely, the fall in the systolic blood pressure during anoxemia is accompanied by a decline in the pulse rate or by a complete failure of the organism to increase its pulse rate under anoxemia. But this is not always the case. Figure 4 shows a record in which a very marked drop in systolic blood pressure occurs during anoxemia which produces a condition approaching collapse, while at the same time the pulse rate increases tremendously. We are probably not mistaken in assuming the circulatory conditions in this case to be similar to those described in the other experiments, since in both types of reactions collapse may ensue. That a very rapid pulse is associated with a decrease in minute volume, has frequently been shown to be true under conditions of oxygen want (Barcroft²⁷).

As the description of various experiments has shown, the main difference in the experiments with 8 and 8.5 per cent O_2 with and without 3 per cent CO_2 lies in the fact that the systolic blood pressure falls in anoxemia to a relatively low level, thereby endangering the blood circulation through the brain. In the presence of 3 per cent CO_2 , however, this reaction is more or less completely prevented, and the systolic blood pressure remains either normal or even slightly elevated. A summary of several such experiments is presented in figure 5.

Fig 5 The effect of 8.5 per cent O_2 and 8.5 per cent O_2 plus 3 per cent CO_2 respectively on four different subjects in erect posture

Figure 6 represents an experiment carried out on subject F, whose record was shown in figure 2. The only difference between the two experiments is that, while F is standing throughout the whole experiment illustrated in figure 2, he is lying down in the experiment recorded in figure 6. The difference in the reaction of the blood pressure is evident from the comparison of the two records. Equally marked are the differences in the subjective symptoms. Practically all experimental subjects have very little or no complaints whatever during the recumbent position even in those cases where they actually faint or are brought very near to this state in the erect position. As figure 6 indicates, the systolic blood pressure remains practically unaltered. However, a very slight tendency toward a fall is still present in the pure oxygen deficiency experiment and absent in the corresponding experiment with 3 per cent CO_2 . The experiments carried out with other subjects in recumbent position are very similar and, therefore, omitted. The results justify the statement that characteristic differences in blood pressure occur during oxygen deficiency with and without 3 per

cent CO_2 in the erect position of the experimental subjects, whereas in the recumbent position no such differences in blood pressure exist

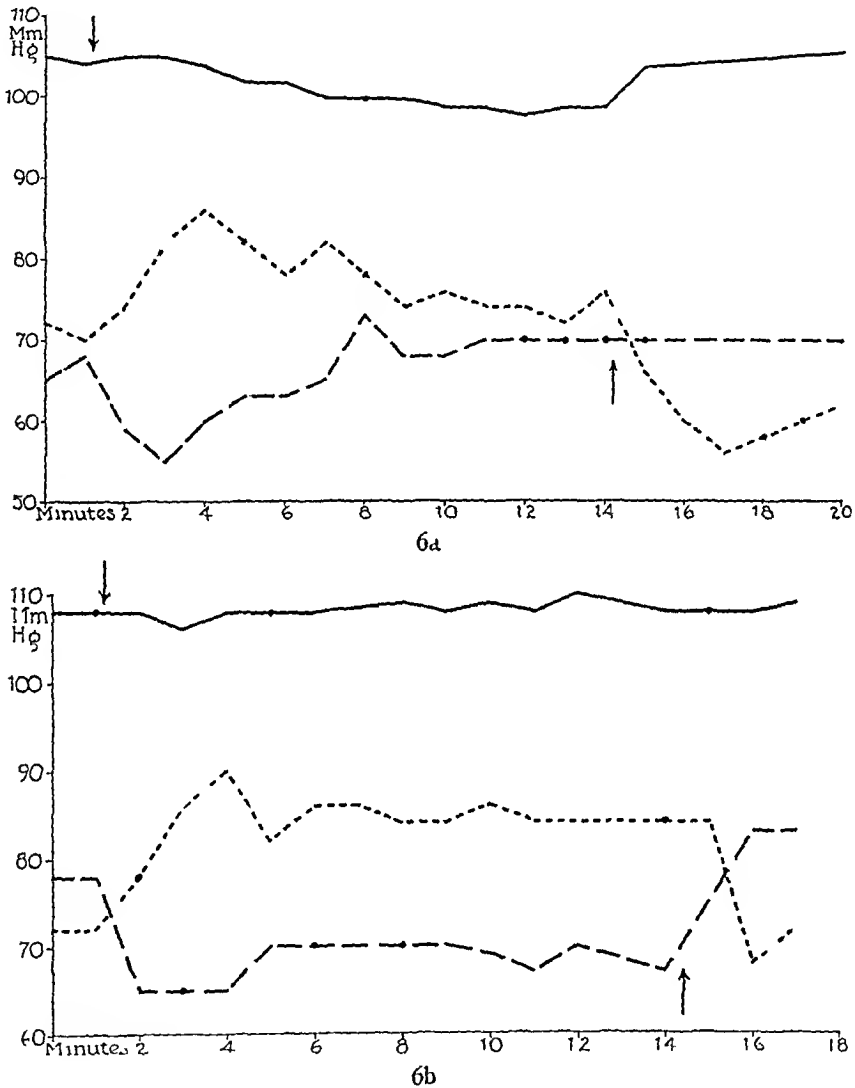

FIG 6a and 6b 85 per cent O_2 and 85 per cent O_2 plus 3 per cent CO_2 respectively between arrows (Subject Fa, lying down)

DISCUSSION

The first question to be answered is the rôle of acapnia in the differences existing in the oxygen deficiency experiments with and without the presence of 3 per cent CO_2 . It is, of course, clear that in the absence of CO_2 the increased respiration resulting from O_2 want leads to a certain degree of acapnia, and it is known, from numerous papers of Henderson,¹³ that under the influence of acapnia the venous return to the heart is diminished and that, consequently, the systolic blood pressure decreases. The question is to decide what importance must be attributed to this factor under the conditions

of our experiments. Therefore a series of experiments was performed in which the experimental subjects voluntarily increased their respiratory volume to a degree similar to that observed under conditions of O_2 want. As table 1 indicates, the greatest drop in blood pressure observed under these

conditions is negligible in comparison to the decrease in blood pressure present in our O_2 want experiments. It may, therefore, be said that a certain degree of acapnia may have almost no effect on the systolic blood pressure when the oxygenation of the blood remains normal. If, however, oxygen deficiency and acapnia are combined, as was the case in the main experiments described in this paper, the reduction in blood supply to the brain, resulting from the acapnia (Cobb and Fremont-Smith,⁹ Schmidt²⁴), aggravates the condition of anoxemia in the central nervous system to such a degree that the blood pressure falls, particularly when the erect posture favors anoxemia of the brain.

Although we believe, as will be shown later, that the major rôle in the decrease of blood pressure observed under conditions of O_2 want in erect posture is played by the carotid sinus, it is to be expected that the vasomotor center as such is of considerable importance. If this is the case the results mean that the loss of CO_2 interferes with the maintenance of the normal tonus of the vasomotor center more under the conditions of anoxemia than under conditions of normal oxygenation of the central nervous system. This implies that CO_2 increases the blood pressure more in anoxemia than under control conditions. This inference has been tested directly in dogs in as yet unpublished experiments (Gellhorn and Lambert¹¹) and shown to be true. Carbon dioxide increases considerably the blood pressure in dogs which are subjected to O_2 want, although the same concentration of CO_2 may not have any effect on the blood pressure as long as the dog is breathing air.

What then is the final mechanism of the difference in blood pressure under conditions of O_2 want in the absence and in the presence of 3 per cent CO_2 ? Since the blood pressure records show no significant differences in the two conditions in a recumbent position, it must be inferred that the main

factor producing these differences is elicited by the erect posture. Now we know that if we change from the recumbent to the erect position there is a temporary decrease in blood pressure in the carotid artery. This, in turn, brings about a restoration in the blood pressure due to the carotid sinus (and aortic nerves) reflexes. It seems, therefore, that under the conditions of anoxemia these reflexes do not function satisfactorily and that CO_2 is a very potent factor to restore them to normality.

The syndrome which we have observed is similar to that of orthostatic hypotension. Here too the change from the recumbent to the erect posture leads to a very considerable drop in blood pressure. The investigations of Alvarez and Roth (1935) have shown that the efferent path of the sympathetic seems to be somewhat affected, at least in one of the cases studied, and this could at least partially account for the decrease in blood pressure in the erect position. The authors, however, feel that these changes are not sufficient to account for the complete syndrome and mention the possibility "that in this disease of orthostatic hypotension there is some defect in the blood pressure regulating mechanism situated in the carotid sinus, but as yet there is no information on that point." The importance of this mechanism is apparent from clinical observations on hypersensitivity of the carotid sinus when under the influence of mechanical stimulation of the carotid sinus a decrease in systolic blood pressure occurs (Smith²⁵). On the basis of these observations and of our own findings, we think it very probable that the carotid sinus mechanism is deficient under O_2 want, due to an insufficient oxygenation of the centers involved, and that the restoration of the circulation in the presence of CO_2 restores these reflexes sufficiently to prevent a fall in blood pressure.

These considerations make it very probable that the carotid sinus (and possibly the aortic nerves) are of primary importance in the explanation of the blood pressure differences observed under conditions of O_2 want with and without CO_2 in the erect position. But we do not believe that this mechanism explains completely all the subjective and objective differences under the two conditions, since characteristic differences remain, at least to a certain extent, even in the recumbent position. In spite of the fact that a certain degree of O_2 want in the erect posture may produce severe headache, weakness, dizziness, a feeling of fullness of the head, paresthesia, impaired vision and hearing and occasionally nausea, it may cause practically no symptoms in the reclining position whether CO_2 is present or not. Not infrequently, however, cases are observed in which the same degree of O_2 want does produce symptoms of slight dizziness, feeling of warmth and disturbances of special senses (the objects in the room appear darker or purplish, the hearing is slightly impaired) in the recumbent position whereas no symptoms may be elicited in the added presence of 3 per cent CO_2 . This difference is, of course, due to the fact that 3 per cent CO_2 improves the oxygenation of the tissues in general and of the brain in particular. It does so by

- 1 An increase in the respiratory volume
- 2 The right shift in the oxygen dissociation curve (Barcroft³)
- 3 The improved venous return due to the increased muscular tonus (Henderson, Oughterson, Greenberg and Seattle¹⁴)
- 4 The specific effect of CO₂ on the blood vessels of the brain (dilatation), (Cobb and collaborators^{8, 12, 19})
- 5 The increased sensitivity of the vasomotor center to CO₂ under conditions of oxygen want (Gellhorn and Lambert¹¹)

SUMMARY

The influence of O₂ want (8 to 8.5 per cent O₂) with and without 3 per cent CO₂ has been studied in the human in the erect and recumbent positions with respect to blood pressure and pulse rate. The results are as follows:

1 In the recumbent position there are practically no differences between the periods of O₂ want and O₂ want plus 3 per cent CO₂. The blood pressure remains unchanged. The pulse rate is slightly increased in either case.

2 In periods of O₂ want the systolic blood pressure shows, in the erect position, a temporary rise which is followed by a fall below the control values. This fall may lead eventually to collapse. In the presence of CO₂ this is prevented and the systolic blood pressure remains elevated throughout the whole period of O₂ want.

3 The changes in diastolic blood pressure are not constant. The pulse rate shows great variability, in most subjects it follows the blood pressure changes. Collapse may, however, occur even during periods of maximally increased pulse rate.

4 The subjective symptoms of anoxemia are more severe in the erect than in the recumbent position. CO₂ may, in either position, completely prevent, or at least greatly diminish, the occurrence of anoxic symptoms.

5 The aggravation in subjective and objective signs of anoxemia, if the experiment is carried out in the erect position, is thought to be due to the failure of the carotid sinus reflexes under the conditions of oxygen deficiency. The addition of 3 per cent CO₂ to the O₂ deficient gas mixtures under these conditions seems to exert its beneficial effect on the objective and subjective signs by improving the oxygenation of the medullary centers and thereby restoring the carotid sinus reflexes to normal.

6 The effect of a certain degree of acapnia on blood pressure is much greater under anoxic than under normal conditions.

DEATH COMPLICATING THE WITHDRAWAL OF NARCOTICS, WITH RESPIRATORY DIFFI- CULTIES PREDOMINANT. REPORT OF THREE CASES¹

By PHILIP PIKFR,² M D, and JULES GELPERIN, B M,
Cincinnati, Ohio

DURING the past three years we have seen three dramatic deaths in narcotic addicts who had been suddenly deprived of the drugs to which they had become habituated

A search through the literature for descriptions of and explanations for such occurrences has been singularly unproductive³. In writing on the subject of morphine withdrawal, many authors have commented on the possibility of collapse, particularly as a complication of sudden withdrawal. Their comments, however, have been uniformly casual and incidental, and in no instance have we been able to discover a specific case report. Several general descriptions of the symptoms likely to occur in such collapse were noted, but here again the literature proved disappointing, since none of these brief general references to the manner of death in this type of case mentioned the occurrence of any outstanding respiratory symptom and since practically all of them spoke chiefly of circulatory collapse. It is because of an unusual finding in connection with the respiration in all three of our cases, the absence of circulatory collapse except just before death, and the scarcity of reported detailed material regarding such cases, that this report is being made. On the occasions when our cases were under observation, we had no thought of publishing data concerning them, so that the laboratory investigations were not as numerous as they otherwise might have been. Only one of the cases was studied in some detail. We submit this report with the hope that interest in the subject will be stimulated, and that more information regarding it will be forthcoming.

CASE REPORTS

Case 1 F H, white male, aged 44, admitted May 7, 1936. The patient had been in the hospital on three previous occasions, the first time in order to break the morphine habit, the next two times to be "cured" of paregoric addiction. In each instance sudden withdrawal was accomplished in a thoroughly satisfactory manner.

* Received for publication November 30, 1936

From the Psychiatric Division of the Cincinnati General Hospital

¹ Alfred M. Stern, Assistant Professor of Psychiatry, University of Cincinnati College of Medicine

² Personal communications from Hans Schwarz of Berlin, Germany, and Manfred Sakel of Vienna, Austria, inform us that those investigators, despite much contact with the subject of morphinism, know of no pertinent information regarding sudden death in this connection, either from their own clinical observation or their acquaintanceship with the literature. We would also like to acknowledge the assistance of Dr. Fritz Moellenhoff, whose knowledge of the foreign literature on the subject was of much help in surveying the field of available information.

with the aid of insulin and ordinary sedatives. Previous to the hospitalization under discussion he had been taking large quantities of paregoric regularly for almost a year. During the two weeks previous to admission, in anticipation of another "cure," he had diminished his paregoric ingestion to two to three ounces per day, and in addition, he had obtained 10 to 15 units of insulin three times per day from his private physician during this two week period.

He was admitted to the ward at 7:30 p.m., walking. He had no subjective complaints other than of a feeling of mild apprehension. He had had his last dose of paregoric at about noon of the day of admission. Physical examination revealed no significant findings except for moderate malnutrition. He was given 15 units of insulin one hour after admission, and 3 drams of paraldehyde one hour later, shortly after which he fell asleep. His sleep, checked at half-hour intervals, was normal until 2:30 a.m.—seven hours after admission, and about 18 hours after his last dose of paregoric. At this time he was found in coma. The significant findings were as follows:

Physical. Temperature 102° F, pulse 80, respiration 48. Respiration peculiar (described under Comment). Pupils dilated and fixed to light. Pulse regular, of good quality. Pulmonary edema. Generalized cyanosis. Blood pressure normal. No significant neurologic findings, save those that would be expected in profound coma. No response to painful or other stimuli. The pulmonary edema responded to atropine.

Urine. Clear amber, sp. gr. 1.030, albumin negative, sugar negative, acetone mildly positive. Microscopic examination negative. *Blood.* Wassermann test negative. Red blood cells 3,900,000, hemoglobin 85 per cent, white blood cells (24 hours after onset of coma) 32,000, with 84 per cent polymorphonuclear leukocytes, 2 per cent lymphocytes, 1 per cent monocytes, and 13 per cent metamyelocytes. CO_2 combining power—16 vol. per cent (4 hours after onset of coma). Urea nitrogen, 21 mg. per cent (4 hours after onset of coma). Sugar, 235 mg. per cent (two hours after intravenous glucose). Phosphorus 2.5 mg. per cent. Chlorides 490 mg. per cent. Non-protein nitrogen 25.6 mg. per cent.

Spinal fluid. Clear, colorless, moderately increased pressure. Globulin normal. Cells normal. Sugar 110 mg. per cent (2 hours after intravenous glucose). Chlorides 750 mg. per cent. Wassermann test negative.

Roentgen-ray of chest (19 hours after onset of coma) negative.

The medications used during the coma were hypertonic glucose intravenously and by hypodermoclysis, physiologic saline by hypodermoclysis, intravenous and intramuscular calcium gluconate, subcutaneous atropine sulphate, caffeine sodium benzoate, and insulin, and intravenous and intramuscular aminophyllin. Morphine was started seven hours after the onset of coma and given in 1/4 to 1/6 grain doses every four hours thereafter, without effect.

Course. The patient remained in coma until death intervened on May 10, 1936. His temperature rose steadily to 107° F, and his pulse rate to 160+. His respiratory rate fluctuated between 30 and 48 per minute. On the second day of the coma he had a generalized convulsion lasting five minutes. Bronchopneumonia was noted several hours before death occurred, and circulatory collapse manifested itself during the last few hours.

Autopsy. Gross findings were lobular pneumonia, toxic changes and chronic passive congestion of the viscera, aortic atherosclerosis, possible early coronary sclerosis, early fatty infiltration of the liver, and cerebral congestion and edema. Microscopic findings were lobular pneumonia, toxic changes in the viscera, early generalized arterio and arteriolar sclerosis, heart negative except for toxic myocardosis, focal necrosis and fatty infiltration of the liver, chronic prostatitis with hyperplasia, cerebral congestion and edema, chronic leptomeningitis, and early degenerative changes in the pons.

Case 2 M H, white male, aged 36 The patient had been taking 18 grains of morphine intravenously per day During the week previous to admission to the hospital, he had been drinking excessively, and had not been able to obtain any narcotics His condition suggested an impending delirium tremens for the first two days in the hospital, and he manifested no symptoms that might have been interpreted as specifically due to withdrawal of narcotics Two days after admission he was found in deep coma and breathing peculiarly Physical examination revealed generalized cyanosis, pulmonary edema, marked generalized muscular irritability, and fixed dilated pupils No other significant physical or neurologic findings were noted The circulation seemed adequate Only ordinary delirium tremens treatment (spinal fluid drainage, dehydrants, fluids, caffeine, and ordinary sedatives) had been used previous to the onset of coma Thereafter, atropine was given as indicated for the pulmonary edema, insulin and intravenous hypertonic glucose were used irregularly, and morphine was administered every four hours Both the coma and the unorthodox respiration fluctuated irregularly, and seemed to bear no relation to the medications administered Morphine apparently had no effect The patient was frequently delirious between comatose periods, and had numerous generalized convulsions The basic neurologic picture did not change The temperature rose to 106° F, the pulse to 150, and the respiration to 52, two days after the onset of the coma, thereafter all three subsided to close to normal for a day, and then steadily mounted, the temperature to 108°, the pulse to 160+, and the respirations to 64 At this time, six days after the onset of coma, evidences of terminal bronchopneumonia and circulatory collapse were observed and were followed shortly by the patient's death The blood and spinal fluid tests gave no evidence of syphilis An autopsy was not performed

Case 3 E P, a white male, aged 49, had been taking 1½ grains of heroin intravenously per day He took his last dose three days prior to hospitalization On admission at 12 30 a m he was found to be in good physical and mental condition, and complained only of cramp-like pains in the abdomen He was given paraldehyde, and soon was sleeping peacefully At 3 30 a m (three hours after admission) his unusual respiration was noted, and he could not be aroused Stimulants were given without effect No other medications were given during the patient's stay in the hospital Morphine was not administered He died two hours after the onset of coma Autopsy was not done No further details were reported on the patient's record

COMMENT

In the cases reported, the outstanding clinical manifestations common to all three were coma, an unusual respiratory disturbance and death We would like to call attention again to the respiratory phenomenon, for which we can offer no explanation The respiration was irregular in rhythm and uniformly deep Periods of apnea of varying lengths (up to 1½ minutes) occurred at irregular intervals, to be followed immediately by deep, gasping inspirations during which all the accessory muscles of respiration were put to vigorous use The expiratory phases were not particularly forceful Generalized cyanosis was quite marked These dyspneic periods fluctuated in duration in the same patient, lasting from five minutes to several hours During the intervals between the attacks of dyspnea, which also varied in length, the cyanosis diminished The administration of morphine sulphate subcutaneously had no appreciable effect It was thought that subcutaneous caffeine-sodium-benzoate occasionally lessened the respiratory distress for

short periods. Though the respiration suggested the Cheyne-Stokes type of breathing in some respects, it was by no means typical. All the clinicians who observed these cases agreed that the respiratory difficulty was almost certainly central in origin. Gross and histologic study of the medulla on postmortem examination of the only one of these cases that came to the autopsy table revealed no enlightening pathology. Whether the degenerative changes present in the pons offered a significant clue was not clear to us. It is known that the depressing effect of a poisonous dose of morphine on the respiratory center of the frog will eventually result in a type of respiration which is somewhat like that seen in our patients. This fact, however, does not explain why abrupt withdrawal of the poisonous substance should produce a similar result.

Another aspect of the problem which has seemed to us to be worthy of emphasis is the fact that the unusual respiratory behavior was common to the three cases despite the existence in each case of factors which made it distinct from the others. The type of opium derivative to which each was habituated, the time between the patient's last dose of drug and the onset of coma and respiratory difficulty, the non-narcotic medication given before and after the onset of the coma—these and other factors varied markedly in the three cases. To us these differences served to make the common findings stand out even more prominently.

We would also like to point out that the circulatory failure so frequently mentioned in the general discussions in the literature as being an outstanding manifestation of the collapse of narcotic withdrawal, did not occur in those two of our patients concerning whom we have adequate information recorded (save as a terminal phenomenon).

Finally we would like to stress that, contrary to a notion that seems to prevail among many clinicians, withdrawal of narcotics from addicts may be complicated by death sufficiently frequently to indicate first, the need for considerable care in the selection of cases for withdrawal and of the choice of method of withdrawal for individual patients, and second, the necessity for diligent clinical observation of patients during the course of withdrawal.

SUMMARY

- 1 Three cases are presented, in which death complicated the sudden withdrawal of narcotics from addicts (*morphine*)
- 2 An unusual respiratory disturbance, common to the three cases, is described (*central type*)
- 3 The absence of circulatory collapse in these cases is pointed out

FATAL IODINE POISONING A CLINICO-PATHOLOGIC AND EXPERIMENTAL STUDY

By REUBEN FINKELSTEIN, M D , F A C P , and MENDEL JACOBI, M D ,
Brooklyn, New York

It is noteworthy that although iodine is used so extensively, comparatively few cases of death through its use have been reported in the medical literature. American medical literature, in particular, contains very few references to either fatal or non-fatal iodine poisoning.

Up to 1911 Witthause¹ found in the literature only 31 cases of poisoning by iodine. Reports from the Westend Hospital in Berlin show that during the years 1912 to 1925, of 1838 cases of poisoning only one instance of iodine poisoning is recorded, the patient recovering.² Non-fatal iodine poisoning following the oral administration of iodine-containing dye for gall-bladder visualization has been recently reported by Davis and Ross.³ A remarkable case of iodine poisoning with recovery is described by Lejbowsch.⁴

The symptoms of acute iodine poisoning are varied. According to Webster,⁵ the local application of an iodine preparation results in a brownish discoloration of the skin with a desquamative dermatitis which may become purulent. When taken internally, the mucous membranes of the mouth, esophagus and stomach are colored brown. The patient vomits a fluid which is usually brownish, but which is colored blue if the stomach contains starches or if the patient is given starch water as an antidote. The bowels move frequently, passing liquid stools, occasionally with mucus. The pulse becomes weak, urinary retention generally results. In fatal cases anuria develops, followed by delirium, stupor and finally collapse.

Bastedo⁶ describes an iodide fever which may develop even after the local application of an iodine ointment. A few deaths due to the therapeutic use of iodine have been reported.^{7, 8, 9}

Numerous instances of poisoning have occurred due to mistakes in accidentally substituting iodine for other darkly colored medicine. Usually the mistake is noticed immediately and prompt action usually averts a fatal ending.

Suicidal intent is responsible for most of the fatal iodine poisonings. With suicide in mind the individual usually takes a tremendous dose, or else delays calling for help sufficiently long for treatment to be of no avail.

* Received for publication November 19, 1936

From the Medical and Pathological Departments of the Beth-El Hospital, Brooklyn, New York, and Office of the Chief Medical Examiner of New York City, Dr. Thomas A. Gonzales, Acting Chief Medical Examiner.

† Assistant Medical Examiner, City of New York.

From the above reports it is apparent that deaths from iodine poisoning fall into three groups

Group I Medicinal use, internally, by injection or by local application

Group II Ingestion of iodine by mistaking it for another drug

Group III Ingestion with suicidal intent

Studying the records of the Medical Examiner's Office of New York City for the past six years, we found 18 instances of suicide by iodine. Of these cases, 13 were males and five females. Death occurred usually within 48 hours after taking the iodine solution. In two instances death resulted within one-half hour and one hour respectively. One individual died after 52 days, following an operation for stenosis of the esophagus which resulted from the ingestion of the iodine. The amount taken, recorded in only nine cases, varied between one and eight ounces of the tincture.

All 18 cases came to necropsy. A number of anatomical diagnoses were made in each instance but the principal causes of death were as follows

Pneumonia	six cases
Pulmonary edema	three cases
Cardiac failure	three cases
Asphyxiation	one case
Peritonitis	one case
Acute corrosive gastritis	one case
Acute ulcerative colitis	one case
Acute parenchymatous degeneration of the liver	one case

In one case the direct cause of death could not be determined because of the condition of the body.

Of the few cases reported in the literature, edema of the glottis is mentioned frequently as the cause of death. One patient was saved by a prompt tracheotomy.¹⁰ In our series of 18 patients only one died as a result of asphyxiation.

In four cases no tests for iodine were made. In two cases in which no iodine was found either in the stomach contents or in the liver, one patient had died 12 hours and the other 52 days after the ingestion of iodine. In the remaining cases, iodine was found in the stomach alone six times, in the liver alone twice, in the stomach and liver twice, in the stomach, liver and kidneys once, and in the jejunal contents and liver once. In this case (number 10) an old gastro-jejunostomy opening was found. Of the two cases in which iodine was found in the liver and not in the stomach contents one had died after 49 hours (number 14), the other (number 8), after 61 hours.

Not all of the above cases presented similar pathologic changes. Iodine is a cell poison, although the slowest acting of the halogen group. Because iodine combines readily with starches, proteins and unsaturated fatty acids forming stable combinations, much of the ingested iodine may become bound to any of these food substances present in the stomach. Since such compounds are but poorly and slowly dissociated their toxic effects are lessened or the drug rendered totally inactive. The minimum lethal dose

(in man is not known. Death has been caused by 20 grams of iodine, and recovery has followed the taking of 150 grams¹¹

Table 1 gives a resumé of the chief anatomical findings of the 18 cases found in the Medical Examiner's Office. As far as could be ascertained from the protocols the extent of the pathologic changes in the organs bore no relation to the length of time between the ingestion of the drug and death. It will be noted that in all but four cases (numbers 6, 7, 9 and 18) the stomach mucosa was affected, the degree of change varying from simple staining to complete necrosis and edema of the wall. In no instance was there any perforation, although in one case (number 8) the stomach wall was noted as abnormally thinned. In those cases in which the amount of ingested iodine was determinable, there was no parallelism between the amount ingested and the degree of gastric involvement, nor was there any apparent parallel between this and the amount of iodine found in the gastric contents, either as free iodine or in combined form (see case 18). The duodenum was involved 11 times, the degree varying from congestion to widespread mucosal necrosis. As with the stomach, there was no apparent correlation with the amount of iodine ingested. It will, however, be noted that, with the exception of case 14 in which four days elapsed before death, the duodenum was involved only in those cases wherein death ensued within a few hours after the ingestion of the drug. The small intestine showed mucosal involvement in only three instances, while the colon showed ulceration of the mucosa only in the case of a patient who had lived for five days after taking the iodine. In view of the fact, however, that two other patients in this series survived for longer periods and showed no such colonic lesion this case must be considered exceptional, especially since no similar finding has been recorded in the literature.

The liver showed gross changes in 14 instances. In five cases there was congestion alone, in six gross fatty changes, in four marked cloudy swelling. Histologic examination was available only in our own case (*vide infra*) in which extensive fatty changes were noted. As with the stomach, the amount of iodine or iodide in the liver could not be correlated with the changes noted. Thus, in case 14, 11.5 mg. of iodine were found in 1000 gm. of a liver that grossly showed fatty changes, while in case 10, with 86 mg. of iodine in 500 gm., the liver was merely congested. In this series of cases, there were apparently no gross changes in the gall-bladders, nor do we find any record of clinical determinations for iodine in gall-bladder bile. That these findings may have been complicated by the treatment given the patient is suggested by case 3. In this case a definite history of iodine ingestion was obtained. At autopsy a severe corrosive gastritis and esophagitis was found, one of the most severe in the entire series, coupled with marked cloudy swelling of the liver. Detailed chemical studies of these viscera failed, however, to reveal any trace of free or combined iodine, or other poison, and it was later learned that repeated intensive

TABLE I
Summary of Gross Pathological Changes Observed in 18 Autopsied Cases Found in Medical Examiner's Office

Case No	Duration of Life	Amt Iodine Ingested	Gross Pathological Changes Observed in								Weight of kidneys	Iodine Found
			Lungs	Stomach	Duodenum	Small Intestines	Colon	Liver	Gall Bladder	Kidneys		
1	12 days	Un known	Discrete hemorrhages lower half	Mucous membrane dark hemorrhage	Not noted	Not noted	None	None	None	Cortex pale	500 gm	Not examined
2	10 hours	6 ounces	Mucous membrane stained dark brown flaky and strand like desquamation near cardia	Scattered hemorrhages in smooth mucous membrane with absent rugae	None	None	None	None	None	Cortex pale smooth	300 gm	None in liver kidney stomach contents
3	13 hours	Un known	Shale gray, dry cooked mucous membrane swollen with Mucous membrane easily separable	Gray blue cooked mucous membrane easily separable, eroded near incisura	Mucous membrane patchy blue gray, submucosal vessels thrombosed	As for duodenum	None	Glazed markings not distinguished	None	Congested	205 gm	None in brain liver kidney stomach contents
4	Few hours	3 ounces	Mucous membrane white easily separable dry cooked membrane	Mucous membrane extensively corroded esp along lesser curvature, light gray granular easily separable membrane	Gray friable mucous membrane	As for duodenum	None	Congested markings indistinct	None	Congested	Normal	Large amounts combined iodine (iodide) in gastric contents no free iodine other organs not examined
5	Few hours	Un known	Not noted	Edematous, congested wall, mucous membrane thickened gray black	Patchy necrosis of mucous membrane with extensive intramucosal hemorrhages	None	None	Flabby fatty markings indistinct	None	Markedly congested	200 gm	Not examined
6	52 days	Un known	See detailed report in text	None	None	None	None	Fatty	None	Congested	370 gm	Not examined
7	38 hours	3 ounces	Not noted	None	Not noted	Not noted	Not noted	Normal	None	Pale cortex markings indistinct	Normal	No iodine or iodide in liver and kidney
8	2 days	3 ounces	Mucous membrane largely necrotic, well reddened thinned	Mucous membrane necrotic yellow brown especially along lesser curvature, wall markedly thinned	None	None	None	Fatty	None	Pale cortex	360 gm	Early large amount of iodide in liver
9	5 days	1 ounce	Not noted	Normal mucous membrane and wall	None	None	Ulcerative colitis	Glassy fatty	None	Pale edematous	Somewhat enlarged	Not examined

TABLE I—Continued

Case No	Duration of Life	Amt Iodine Ingested	Gross Pathological Changes Observed in							Weight of Kidneys	Iodine Found
			Esophagus	Stomach	Duodenum	Small Intestines	Colon	Liver	Gall-Bladder		
10	4 hours	Un known	None	Submucosal hemorrhages	Terminal duodenum and adjacent 4 ft. of jejunum acutely inflamed, mucous membrane covered by extensive gray friable separable membrane. Case had had antecedent partial gastrectomy	None	None	Congested markings indistinct	None	Not noted	Liver 86 mg iodine in 500 gm tissue Jejunum contents 122 mg free iodine in 20 c c
11	Un known	Evidently 8 ounces	None	Corroded mucous membrane	Autolytic mucous membrane	None	None	Autolytic	Autolytic	Not noted	Liver 31.5 mg iodine in 500 gm tissue Kidney 5.6 mg iodine in 100 gm tissue Stomach 156 mg iodine in total Not examined
12	1 to 1½ hours	Un known	Not noted	Mucous membrane necrotic throughout	Congested	None	None	Congested markings indistinct	None	Not noted	Absent in kidney
13	2 days	1 ounce	Not noted	Mucous membrane stained brown throughout, occasional petechial hemorrhage	Not noted	Not noted	None	Congested markings indistinct	None	Not noted	
14	4 days	2 ounces	Mucous membrane pitchily eroded	Mucous membrane markedly swollen hemorrhagic	Congested	None	None	Congested fatty	None	In large	Liver 21.5 mg iodine in 500 gm tissue
15	3 hours	Un known	Not noted	Mucous membrane gray brown soft not eroded	Congested	None	None	Congested	None	Not noted	Free iodine present in fairly large amounts in gastric contents Iodides present in fair amounts in liver
16	1 hour	¼ pint	Not noted	Mucous membrane caked uniformly brown red	As in stomach	None	None	Congested	None	Not noted	Large amounts free iodine in gastric contents
17	2 hours	Un known	Not noted	Mucous membrane thick, gray parched patchily blackened and eroded	Markedly congested	Mucous membrane of upper jejunum markedly congested	None	Fatty	None	Normal	Large amounts free iodine in gastric contents
18	7 hours	Un known	Not noted	Normal	Mucous membrane stained brown contains small amount of blood	None	None	Fatty	None	Normal	Iodide 24.4 mg in gastric contents 11.5 mg in 1000 gm liver tissue

lavage of the stomach with starch and milk had been performed early in the treatment

In all but three instances the kidneys showed pallor, congestion, or indistinct markings. In two instances the cortex was noted as swollen, in one as indistinguishable from the medulla. Here again neither the amount of iodine ingested nor that found in the kidney nor the time interval between ingestion and death could be correlated with the gross anatomical findings. Histologic examination was done only in case 2, in which there was found intense congestion of the interstitial capillaries, and red cells and red cell casts in the collecting tubules. There was intense, but rather patchy, congestion of the glomerular capillaries, this contrasts with the findings in our own case in which the glomeruli were chiefly bloodless and their lumina apparently occluded by the swollen endothelial cells in apposition. This apparent morphological difference may be due to the difference in the length of life after the iodine ingestion. The longer duration in our case may have accounted for the reactive cellular changes observed in the glomeruli, the ischemia being due to the mechanical occlusion of the lumina by the swollen cells in apposition—a change obviously requiring more than the few hours interval present in case 2. In neither instance were there gross changes suggesting an acute diffuse glomerulo-nephritis or isolated glomerulitis nor was there histologically any increase in endothelial, epithelial or interstitial cells, no thickening of the basement membrane, nor any evidence of inflammation.

With material such as ours, dependent as it necessarily is on clinical reports from a number of institutions—which are never detailed and are frequently confined to a mere statement of the fact of iodine ingestion and its apparent intent—any analysis of symptoms is not entirely satisfactory. Nevertheless, anuria appears in the records twice (cases 1 and 9) and a clinical diagnosis of uremia once (case 9). These two cases are among those of longest duration in the series, respectively twelve and five days.

Because of the incompleteness of the data, an attempt was made to determine experimentally the effects of iodine on the kidneys. Two rabbits were given respectively 5 c c and 3 c c of tincture of iodine intravenously. The first rapidly went into shock and died in four hours. At autopsy no gross or histologic renal changes were apparent except for marked congestion of the glomerular and interstitial capillaries and a slight degree of cloudy swelling of the convoluted tubular epithelium. The liver showed moderate cloudy swelling, the cardiac muscle fibers were markedly swollen, the striations indistinct and markedly fragmented. The gastric mucosa was reddened but not eroded.

The second rabbit lived 24 hours. At autopsy, the renal, cardiac and hepatic findings, both grossly and microscopically, were identical with those noted in the first rabbit. The gastric mucosa of the pyloric half of the stomach showed a widespread ulceration and brownish discoloration of the

mucosa The ulcer was shallow and covered by a friable, necrotic brownish membrane which, when separated, revealed the ulcer base formed by the reddened muscularis Its edges were formed by reddened, edematous mucosa which was easily separable from the gastric wall On section, the ulcer was covered by necrotic mucosa and a leukocytic debris In the superficial layer of the muscularis were thrombosed veins with necrotic walls Chemical examination of the gastric contents revealed iodine in organic combination

Two other fasting rabbits were given 5 c c of tincture of iodine by nasal catheter (under fluoroscopic guidance) intragastrically These exhibited no untoward symptoms and lived for one week and 10 days respectively At autopsy, mucosal necrosis of the gastric fundus near the pylorus was noted in each rabbit as well as of the adjacent duodenum No gross or histologic renal changes were present The liver showed marked and widespread fat phanerotic changes, involving the greater part of each lobule The heart muscle showed considerable cloudy swelling The urea nitrogen had risen from 16 mg per cent to 41 mg per cent before death

Because of the presence of only moderate congestive glomerular findings, both in the human cases and in the experimental animals, it is doubtful whether the apparent uremia was of renal origin In most cases of iodine ingestion, severe and protracted vomiting or gastric lavages, often repeated, result in the loss of large quantities of electrolytes It is doubtful if any electrolytes taken in solution orally can be absorbed through a mucosa so congested, baked, caked, necrotic, or ulcerated as that usually seen in the stomach and adjacent duodenum and occasionally in the small intestines in cases of iodine ingestion Even in those cases where no gross mucosal involvement is present, the intestines are usually dilated and contain large amount of grumous, gray, turbid, or blackened material These findings resemble those present in paralytic ileus There is no question but what serious loss of electrolytes and water will cause renal suppression with a resulting nitrogen retention, a condition long recognized and treated in cases of intestinal obstruction It is further a matter of everyday clinical experience that such a state occurs more rapidly the higher the obstruction In cases of iodine poisoning the pathologic changes are usually in the stomach, duodenum and upper intestine

It has also been shown that urinary suppression and a rise in blood nitrogen can be produced by forced diuresis initiated by repeated injections of sucrose¹² It is possible that glucose acts in a similar manner¹⁸ Yet, in an attempt to spare the liver from damage so frequently present in the cases cited, the intravenous injection of glucose was resorted to in our case, as is usual in clinical practice However, as we have here shown, the kidneys in cases of iodine poisoning already show cloudy swelling and probably increased permeability It can therefore easily be seen how this procedure only increases the dehydration thus further increasing the toxemia It

would be better merely to replace electrolytes by the intravenous route and leave until later in the clinical course the administration of caloric necessities and then by the subcutaneous rather than the intravenous routes. It may even be that the electrolytes and fluids themselves had better be administered subcutaneously as was done by Lejbowitsch.⁴

Of passing interest is the symptom of shock present in 11 of our cases (numbers 1, 2, 4, 5, 10, 12, 13, 15, 16, 17, 18). This may perhaps be associated with the myocardial changes such as were present in our experimental rabbits which were injected intravenously, or this shock may be due to a severe disturbance of the splanchnic nerves due to changes incident to the gastric and duodenal and hepatic lesions.¹⁴

Of interest also is the extremely early development of clinical symptoms and signs of pulmonary parenchymal (pneumonic) involvement, and the pathologic changes even a few hours after the ingestion of the drug. Thus, in case 2 dying about 10 hours after the iodine ingestion, "the trachea and larger bronchi contained a foul smelling, brown material and some yellow creamy pus pouring forth in large quantities from the upper and lower bronchi. The lungs, especially the lower lobes, are irregularly, but widely consolidated, the consolidation being distinctly peribronchial in distribution." In case 3 dying 13 hours after the iodine had been ingested, "the bronchi contained mushy gray purulent contents." It is possible that the gastric necrosis and the vomiting caused more than usual intrabronchial aspiration of gastric contents, and that lavage in the presence of such abnormal peristalsis and the marked relaxation of gastric and bronchial walls allowed of easy ingress of the lavage material into the lungs already the seat of an edema (case 1). No instances are recorded of the presence or absence of bacteria in the gastric contents but it is doubtful whether the ingested tincture of iodine can so rapidly eliminate organisms contained in the stomach.

Case 6 deserves brief individual comment. In this case there was a definite history of the ingestion of iodine with suicidal intent, and the presence of iodine burns of the lips and tongue. With gastric lavage the patient recovered from the acute symptoms, but thereafter gradually but progressively developed symptoms of esophageal obstruction. Esophagoscopy 33 days after the iodine ingestion revealed the mucous membrane just above the cardia to be so scarred as to cause stenosis. After two unsuccessful attempts at dilatation, gastrostomy was performed, the patient dying of a general peritonitis and mediastinitis four days thereafter. At autopsy a transverse puckering of the esophageal mucosa and scarring of the wall were present 3 cm. above the cardiac end of the stomach. The esophageal lumen was so narrowed that a probe 4 mm. in diameter could barely be passed into the stomach. The scarred area involved the entire terminal 3 cm. of esophagus and adjacent 2 cm. of gastric mucosa. The patient lived for 52 days after the ingestion of the drug and hence no chemical analysis for iodine was performed post mortem. However, the history

obtained repeatedly during the patient's lengthy stay in the hospital, as well as analysis of washings from the bottle supposed to have contained the drug ingested, failed utterly to indicate any substances other than iodine. So far as we could ascertain, this is the only recorded case of esophageal stenosis caused by iodine.

CASE REPORT

On May 25, 1935, at about 1 30 p.m., a 29 year old white man was sent to the Beth-El Hospital by Dr. Nathan Davis four days after having taken an unknown amount of tincture of iodine during a period of despondency.

The patient appeared to be fairly well nourished but looked ill. His eyes reacted to light and accommodation, the sclerae were slightly jaundiced. No pathological changes were evident in the nose and throat. Examination of the mouth revealed dry lips and a dry coated tongue with a few ulcerations of the buccal mucosa. The breath presented a peculiar odor.

The expansion of the chest was fair. The respiratory rate was somewhat increased, no râles were heard. The heart was regular in rate and rhythm. The sounds were of good quality and no murmurs were heard. Examination of the abdomen showed some tenderness over the liver region. The rigid recti muscles prevented proper palpation of the liver and spleen. The skin was somewhat cyanotic but no jaundice was noted. The extremities showed no abnormal findings except a slight cyanosis under the nails.

The systolic blood pressure was 140, the diastolic 80, the pulse rate 96 per minute, respiration 24 per minute and the temperature 99.4° F.

On admission to the hospital, five ounces of urine were obtained by catheterization. It was smoky in color, specific gravity 1.010, acid in reaction, albumin 2 plus, glucose negative, and acetone positive, no casts were found, some white and red blood cells and epithelial cells were present. Iodine in organic combination was found in the urine. The blood count showed 5,000,000 red blood cells, 70 per cent hemoglobin, 14,000 white blood cells, with 85 per cent polymorphonuclear neutrophils and 15 per cent lymphocytes. Blood chemistry: glucose 142 mg per cent, urea nitrogen 150 mg per cent, non-protein nitrogen 228 mg per cent, creatinine 7.5 mg per cent, uric acid 5.6 mg per cent, chlorides 556 mg per cent, phosphorus 3.5 mg per cent.

On admission, 250 c.c. of 25 per cent glucose solution were given intravenously and a retention enema of 1000 c.c. of 15 per cent glucose solution and 5 per cent sodium bicarbonate was also given. To rule out a possible gastric perforation a roentgenogram of the abdomen was taken. No evidence of free gas in the abdomen was found. The left kidney appeared larger than the right. There was no evidence of radio-opaque substance in the renal regions.

The first evening after admission the patient vomited a small amount of light brown fluid with bloody mucus, and passed a dark brown liquid stool. That night the patient complained of abdominal soreness. At 11 p.m. the patient was taken to the operating room, 600 c.c. of blood were removed and 450 c.c. of blood were given by direct transfusion. The blood pressure, taken again at this time, was 142 systolic and 60 diastolic. During the remainder of the night, the patient slept very little because of frequent and severe abdominal cramps.

During the second day the patient again complained of severe abdominal pain which was relieved by morphine sulphate. The patient vomited only once during the day. Intravenous injections of 250 c.c. of 25 per cent glucose solution were given during the morning and evening. At midday a solution of 1000 c.c. of normal saline was administered by hypodermoclysis. During the second night, the patient was

restless because of the continued abdominal pain but slept at short intervals. At 11 p.m. another hypodermoclysis of 750 c.c. of normal saline solution was given.

On the third day the jaundice noted in the sclerae on admission had practically disappeared. The abdomen was more distended, some rigidity in the upper right quadrant was noted. Only three ounces of urine were obtained by catheterization. At this time 500 c.c. of blood were again removed and an equal amount of whole blood given by direct transfusion. The patient continued to be restless and slept only at intervals.

On the fourth day 10 c.c. of sodium thiosulphate solution were given intravenously. Anuria developed, colonic irrigations were given with no evident benefit. On the fourth and fifth days the patient continued to be restless but treatment was continued. The blood urea rose to 172 mg. per cent and blood creatinine to 12 mg. per cent. The blood CO_2 was 18 volumes per cent. Sodium bicarbonate in a 5 per cent solution was given intravenously. During the night of the fifth day, the patient became irrational, very noisy and restless. Twitching developed in various parts of the body.

On the sixth day the temperature rose to 104°F , the patient sweated profusely, was still irrational and toward noon sank into coma. General cyanosis developed and the patient died at 6 p.m.

The urine was always dark and smoky, and contained hyaline and granular casts, but no red cells were found on the third day after admission. The temperature on admission was 99.4°F and rose on the third day to 103.2°F fluctuating on the fourth and fifth days and at the close of the fifth day rose to 104.2°F coming down at the time of death on the sixth day to 102°F .

Autopsy Report The body is that of an adult male of about 30 years of age, 62 inches in height, slight in build, weighing about 120 pounds. The pupils are equal and in mid-dilatation. There are no external evidences of injury. On the buccal mucosa just within the lip line several small white ulcerations are present, pinhead to lentil in size. There is no other discoloration of the buccal mucosa, gums or tongue.

The head was not examined.

The thyroid gland is normal in size and shape and weighs 21 grams. On section the gland reveals a finely lobulated appearance and is of a pale brownish red color not unlike skeletal muscle. There is no lymphadenopathy. Nothing unusual is found in the pharyngeal mucosa.

Internally, the esophagus is covered by a thin, friable membrane of a yellowish brown color in its lower third. This membrane strips easily revealing a reddened submucosa. The upper portion of the esophagus is intact.

The pleural cavities contain a small amount of clear yellow fluid. The visceral pleura is reddened and dull but not covered by any exudate.

The lungs are voluminous, heavy, soggy and moderately firm. The firm areas tend to be patchy in arrangement with the intervening areas pale and fluffy. On section the smaller bronchi contain variable quantities of debris (gastric contents). Moderately firm areas varying in size from a lung lobule to a third of the lobe are present and are irregularly distributed throughout the lungs. These areas are drier than the surrounding parenchyma. A definite relationship to the bronchi or vessels is lacking. The cut surfaces ooze large quantities of frothy serosanguinous fluid. The larger bronchi and lower end of the trachea show a red and edematous mucosa but there are no ulcerations or discolorations.

The pericardial cavity contains a few c.c. of clear yellow fluid. The heart is normal in size, shape and configuration. The valves and orifices show no changes. The ventricular muscle is of a deep brownish red color and is unusually soft and flabby. There are no areas of fibrosis or softening. The coronary vessels are soft and pliable.

The peritoneal cavity contains about 1200 cc of clear yellow fluid. The loops of the small bowel are heavy with contained fluid. All peritoneal surfaces are smooth and glistening.

The entire mucosal surface of the stomach is covered with a dirty yellowish membrane which is more pronounced in broad longitudinal streaks (rugae). The membrane strips easily revealing an intensely edematous and congested submucosa. This membrane stops abruptly at the pylorus. The gastric wall is thickened by edema and congestion. There is no exudate on its peritoneal surface. There are no perforations. The duodenum is intensely congested and edematous and stains a deep yellowish brown, but lacks a definite membrane such as is seen in the stomach. The duodenal lesion involves the entire length of the duodenum and a similar but progressively less marked lesion is seen in the first 10 inches of the jejunum (figure 1).

FIG 1 Photograph of fresh liver, stomach and gall-bladder from our own case. The stomach was opened along the greater curvature to show the mucosal surface. Note the widespread necrosis and diphtheritic gastritis at *A*, the necrosis of tops of rugae at *B*, also the relatively intact mucosa of the lesser curvature near the pylorus at *C*. *D* is the liver and *E* the gall-bladder.

The remainder of the small intestine shows distention of the small veins with occasional minute extravasations of blood in the subserosal tissue.

The gall-bladder is markedly distended by an opaque muddy brown liquid of low viscosity. The mucosa of the gall-bladder shows a patchy denudation with ragged edges of mucosa which project into the lumen. The cystic duct, common duct, and hepatic ducts show no changes. The ampulla of Vater is normal.

The capsule of the liver is smooth and glistening. On section the organ shows a nutmeg-like appearance due to a brownish yellow deposit in the periportal region.

The individual lobules are markedly swollen. The general cut surface has a pale yellowish appearance.

The pancreas shows normal lobulation.

The colon is normal. The mucosa and submucosa of the rectum are markedly edematous.

The spleen is large and soft, and weighs 300 grams. The edges and notches are rounded. On section the pulp is everted over the cut edges. The Malpighian bodies are large, hazy and tend to be confluent. The pulp is moderately soft but not diffuent.

The kidneys weigh 160 grams each. The capsules strip easily leaving a smooth surface. On section the cortex is markedly widened and bulges over the cut edges. The cortical markings are hazy. The glomeruli are prominent as pinhead red dots. The medullary markings especially at the cortico-medullary junction are moderately hazy. The pelves and ureters show no abnormalities.

The bladder mucosa is somewhat reddened and edematous. The verumontanum projects into the bladder as a long finger-like structure with a reddened and edematous bulbous ending.

The adrenals show no abnormal findings.

Microscopical Examination. Sections of lung show patchy areas of consolidation distributed throughout all lobes of the lungs with intervening areas of parenchyma showing no changes beyond congestion and intra-alveolar edema. The consolidated portions of the lungs show an intra-alveolar exudate consisting of polymorphonuclear cells, large mononuclear cells and red blood cells and serum. The amount of fibrin in the exudate is minimal. The small bronchioles show complete or partial desquamation of their lining epithelium, their lumens are filled with desquamated epithelial and polymorphonuclear cells. The larger bronchioles show desquamation of the lining epithelium with moderate congestion and leukocytic infiltration of the walls.

Sections of the heart show no changes in the pericardium, myocardium or endocardium. The aorta shows scattered numbers of large mononuclear and wandering cells in the intima. No other unusual changes are noted.

The acini of the thyroid are large, but few are cystic. They are lined by cuboidal epithelial cells and are filled with a fairly homogenous pink colloid material. Many of the acini are smaller in size and contain little or no colloid material. The supporting stroma is moderately increased in amount and contains occasional patchy collections of small round cells.

The liver cells contain numerous fine vacuoles evenly distributed in the cells throughout all parts of the lobules. The cells are not markedly swollen. There are no abnormal cellular infiltrations. The vacuoles are stained bright red with Sudan III, are not stained with Nile-blue sulphate, osmic acid or by the Lorrain-Smith-Dietrich method (vacuoles are fatty acids).

There are no unusual changes in the parenchyma, islands of Langerhans or ducts of the pancreas.

The glomerular loops in the kidney are bloodless. There is, however, no increase in the number of nuclei. In a few glomeruli a slight amorphous intracapsular exudate is found. The cells lining the parietal layer of Bowman's capsule are swollen, occasionally desquamated and tend to be of cuboidal or of low columnar variety. The convoluted tubules show a marked granular cytoplasmic swelling of their lining cells with disintegration of the peripheral half of the cells so that the lumen appears to be markedly widened. Many of the tubules are filled with well preserved or partially disintegrated red blood cells and large quantities of amorphous pigment.

Sections of the spleen show a diffuse reticulum cell hyperplasia and a moderate congestion of the pulp accompanied by small patchy recent hemorrhages into the red pulp.

The stratified squamous epithelium of the esophagus is rigid and tends to break off from the supporting stroma. The superficial layers of epithelium are keratinized. There are no unusual changes in the mucosal layer. The submucosa is moderately edematous and shows in places small focal collections of round cells while immediately beneath the epithelium there is a patchy leukocytic infiltration.

The mucosa of the stomach is almost completely necrotic. Recognizable epithelial cells are present only at the base of the glands. The upper portions of the gastric mucosa are converted into an amorphous eosinophilic mass. The submucosa is intensely congested, edematous and shows numerous lymphatics crowded with polymorphonuclear cells and lymphocytes. The cellular infiltrate extends along the interstitial tissue and vessels through all layers of the stomach including the serosa.

The mucosa of the gall-bladder is edematous. The stroma is markedly infiltrated with polymorphonuclear leukocytes and some lymphocytes. The cellular infiltration extends deeply into the fibro-muscular layer. Occasional lymphatics in the fibrous layer are distended with polymorphonuclear leukocytes.

Sections of the jejunum show necrotic changes in the mucosa with varying degrees of edema and round cell infiltration of the submucosa. The severity of the lesion decreases as the distance from the pylorus increases. Sections of large bowel show no unusual changes.

Sections of skin and subcutaneous tissue show no abnormal changes in the skin or its appendages.

Sections of testicle show all phases of normal spermatogenesis in the seminiferous tubules.

No degenerative changes or loss of the normal striation could be noted in sections of the skeletal muscle.

Chemical examination disclosed large quantities of iodine as inorganic iodine in the liver and kidneys and both as inorganic and organic iodine in the bile. In the bile, tests for iodine were positive only after separation from conjugated proteins.

SUMMARY

1 A case of fatal iodine poisoning, with detailed autopsy findings, is reported. Eighteen other cases are reported from the records of the Medical Examiner's Office of New York City. The infrequency of fatal iodine poisoning is remarked, but it is suggested that the condition is more prevalent than is currently believed.

2 The renal suppression and nitrogen retention occurring during the course of iodine poisoning is discussed. It is suggested that this happening is the result of extrarenal loss of electrolytes and dehydration. No significant renal lesions were found in the human cases or in the animals experimented upon. It is suggested that therapy be aimed at the replacement of electrolytes and water during the acute phase, and that glucose injections or other measures leading to forced diuresis be avoided.

3 The early appearance of shock and aspirational pneumonia are stressed and the possible mechanism discussed.

4 An instance of esophageal scarring and stenosis is recorded, the only one of its kind in the literature.

The authors desire to express their thanks to Dr. Nathan Davis for the earlier clinical data of this case and also to Dr. Thomas Gonzales, Acting Chief Medical Examiner of the City of New York, for permission to report the 18 cases from the Medical Examiner's Office.

THE GALACTOSE TOLERANCE TEST IN JAUNDICE; A CONSIDERATION OF THE EVIDENCE PERMIT- TING THE MEASUREMENT OF GALACTOSE UTI- LIZATION BY URINARY EXCRETION; SOME SOURCES FOR ERROR IN ITS INTERPRETATION; AND AN ADDITION IN ROUTINE TECHNIC

By HARRY SHAY, M D , and PHILIP FIEMAN, M D ,
Philadelphia, Pennsylvania

IN 1931, in a paper on the study of the metabolism of galactose in the human subject, Shay, Schloss and Bell¹ concluded that this hexose was best suited for testing the carbohydrate function of the liver. In order for the urinary excretion of this sugar, orally administered, to act as a measure of hepatic carbohydrate function, they considered the following among the necessary conditions: (1) that there be no renal threshold for the excretion of galactose, (2) that galactose utilization remain unmodified by the activity of those endocrine glands known to affect glucose metabolism, (3) that galactose be practically unutilizable by all tissues other than the liver.

Because of the bearing that these facts have upon our thesis, it is essential to examine the more recent evidence which may lend support to the above.

Some investigators have questioned the use of a fixed dose of galactose for this test. We cannot subscribe to the opinion of Roe and Schwartzman² that it is necessary to employ a dose of sugar commensurate with body weight. Shay, Schloss and Bell¹ have demonstrated that the utilization of galactose is independent of age, weight, or sex. Harding and Grant³ also prefer the fixed dose of 40 grams. Although a test amount of the sugar varying with the body weight or with the body surface may seem more logical and scientific, these authors believe that such a fluctuating dose will give no greater uniformity of results. This belief is supported by a comparison of the results of Harding and van Nostrand,⁴ who used a fixed dose of 50 grams, with those of Roe and Schwartzman⁵ who employed a regulated dose of 1 gram per kilogram of body weight. The urinary excretion of both groups will be seen to show large fluctuations. More recently R. K. Owen,⁶ studying a group of 30 normal subjects (15 male, 15 female) between the ages of 20 and 70, found, after a uniform 40 gram dose, a urinary excretion whose variation and average were similar to those found in the normal group studied by Shay, Schloss and Bell¹.

The improvement in the chemical methods for the measurement of small amounts of galactose in the blood has given rise to the feeling that the

* Received for publication December 11, 1936

From the Gastro-Intestinal Division of Medical Service 1, Mt. Sinai Hospital, Philadelphia

blood galactose curve may be a better measure of galactose utilization than urinary excretion. This would be true if a renal threshold for galactose could be demonstrated. However, the most convincing evidence is against the existence of such a threshold. Fohn and Berglund⁷ first furnished adequate evidence of its absence. They found that very small doses of galactose produced an increase of urinary reducing substances. Later Goldblatt,⁸ studying the blood sugar after galactose administration, observed urinary excretion of galactose in the absence of any rise in blood sugar. Harding and Grant,³ from studies on arterial blood galactose, were convinced that galactosuria can occur with very little rise in blood galactose.

In the absence of a kidney threshold, the blood level of this sugar, so far as the galactose tolerance test is concerned, is of academic interest only. None of the advocates of blood galactose estimations has thus far demonstrated that these are more significant than the measurement of the urinary excretion of this substance in the application of this test to the differential diagnosis of jaundice. We can, therefore, see no reason for converting a valuable laboratory test from a simple office procedure into one almost prohibitive for routine clinical use.

Any liver function test dependent upon the utilization of a sugar must of necessity take into consideration the possible conversion of the test substance in tissues other than the liver. In 1922, Mann and Magath,⁹ while studying the ability of various sugars to combat the hypoglycemia following liver extirpation in the dog, found that injected galactose failed to give any appreciable result. In 1931, Shay, Schloss and Bell¹ demonstrated that in the human subject, after ingestion of galactose, the injection of amounts of insulin capable of producing hypoglycemic blood levels with marked symptoms of hypoglycemia, failed to modify materially the urinary excretion of galactose. Roe and Schwartzman⁵ in 1932 recorded similar results from experiments on dogs.

Following the injection of adrenalin chloride after galactose administration, one of us (H. S.)¹ found a greater output of reducing substances in the urine than had occurred without the adrenalin. However, differential fermentation showed that the extra reducing substances were fermentable, the non-fermentable fraction remaining similar in amount to that excreted when no adrenalin had been used. Further support of the independence of galactose utilization of factors which definitely modify glucose metabolism is shown in the results of Wierzuchowski.¹⁰ He found that the assimilation of galactose by dogs receiving a continuous injection of two grams of this sugar per kilo per hour over a 10 hour period was not affected by the type of previous food, by hunger, by adrenalin or by thyroxin.

Arcq¹¹ working with dogs and cats recorded that galactose, after either intravenous injection or oral administration, will augment hepatic glycogen but will fail to form muscle glycogen in spite of optimal conditions for its formation.

Laquer and Meyer¹² studying suspensions of muscle tissue found that dextrose and levulose were transformed almost quantitatively into lactic acid, while galactose was not converted at all, or in insignificant amounts only.

Griesbach¹³ in muscle perfusion experiments with galactose obtained no evidence of utilization. Very recently Roe and Cowgill¹⁴ failed to find any oxidation or conversion into glycogen of galactose in voluntary muscle tissue. They studied the galactose content of afferent and efferent blood in the leg in the dog following galactose administration.

Mann¹⁵ recovered from the urine more than 80 per cent of intravenously injected galactose in the dehepatized dog and more recently Bollman, Mann and Power¹⁶ have been unable to prevent the onset of hypoglycemic convulsions in the dehepatized animals with relatively large amounts of galactose. Roe, Gilman and Cowgill¹⁷ in 1934, from studies of the effect of the ingestion of galactose upon the respiratory quotient of the normal and depancreatized dog, reported that galactose per se is not oxidized in the dog, that its normal metabolism is conversion to an intermediate (glycogen) which may break down to glucose—a conclusion identical with that recorded by Shay, Schloss and Bell¹ in their studies on the human subject in 1931.

Despite the findings of Sheriff and Holmes¹⁸ that the presence of galactose prolongs the period during which the mammalian nerve consumes oxygen, indications are that this hexose does not play an important rôle in nerve cell activity. Galactose consumption by nervous tissue must be slight in view of the results obtained in depancreatized animals. Thus Kosterlitz and Wedler^{19,20} as well as Bollman and Mann²¹ have recovered in the urine amounts of galactose practically equivalent to those administered to depancreatized dogs. The excretion was recovered partly as glucose and partly as galactose.

Roe and Cowgill,¹⁴ by estimating the galactose contents of the blood samples removed simultaneously from the common carotid artery and from the internal jugular vein in dogs, after galactose administration, failed to obtain any evidence of the oxidation of galactose by nerve tissue.

In the clinical application of the galactose tolerance test certain facts, although previously published,²²⁻²³ must be reiterated. *This test can have no value if applied as a general liver function test. As an aid in the differential diagnosis of jaundice it is of incalculable value.* In the latter it has its greatest usefulness if applied early in the course of the jaundice.

The vital character of the carbohydrate function of the liver demands a large reserve in this organ. The remarkable regenerative capacity of the liver helps restore such a reserve. Impaired carbohydrate tolerance, therefore, becomes manifest only in the presence of acute diffuse liver cell damage, or in chronic damage, when the reserve has been spent and regeneration has failed. When diffuse damage has occurred and repair sets in, the carbohydrate function of the liver appears to be restored with great rapidity even when very little other change is discernible.

The galactose tolerance test, therefore, should be the first laboratory procedure employed in the study of jaundice. It is far more essential as an aid in determining therapy to know the galactose tolerance than it is to determine the number of milligrams of bile pigment in the blood or the icterus index. Aside from the fact that the tolerance should be determined early in the course of the jaundice, it should be repeated in two to three days if the results obtained are borderline. By a borderline reading we mean an output a little below 3 grams in the five hours of the test period.

In our work we have adopted the 3 gram level of urinary excretion of galactose as the upper limit of normal in the five hours after a 40 gram dose of the sugar. This figure we believe represents an adequate margin of safety. We have seldom under such conditions seen a urinary output of more than 2 grams in the normal individual. Owen⁶ has recently reported similar results. Readings between 2.5 and 3 grams, therefore, require a repetition of the test, in order to be able to interpret the results with certainty. Such readings usually occur in very mild forms of acute diffuse hepatitis, in which cases the readings may remain below 3 grams throughout the course of the disease. Then the short duration of the jaundice, the usually slight jaundice, as well as a rapidly diminishing galactose output to definitely normal levels on repeated testing, will indicate the mildness of the affection. Schiff and Senior²⁴ have recently reported such a case.

In other instances the carbohydrate function will be sufficiently disturbed to give a positive galactose test for only a short time and then will quickly return to normal as recovery rapidly sets in. Such cases indicate the importance of utilizing this test early in the course of jaundice. This point is illustrated by the following case.

J. F., aged 52, had been in excellent health until a week before admission when nausea appeared. About the same time jaundice was first noticed. There was no pain. A galactose tolerance test on the day of admission gave a reading of 3.46 grams, two days later a repetition of the test gave an output of only 2 grams, and three subsequent tests were all below 2 grams in spite of the fact that the blood bilirubin decreased very slowly.

Had the galactose tolerance test been delayed for two days, this case would have been classified under the failures for the test. The subsequent course and history indicated that we were dealing with a hepato-cellular jaundice which had had only a short period of disturbed carbohydrate function.

It is certainly no indictment of the test if it is found negative when applied first in the third or fourth week of a toxic hepatitis, at which time liver regeneration and repair in many instances will have been sufficient for the restoration of the vital carbohydrate function. Nor does it seriously impair the value of the test if it is found positive occasionally in an obstructive jaundice of several weeks' duration. By this time the reserve of the liver may have been overtaxed or the jaundice may have become associated with infection of the biliary tree which has had time to spread and

superimpose diffuse hepatic cell damage upon the initial obstruction. We believe that the few unfavorable reports on the galactose tolerance test in jaundice have been due to the failure to apply strictly the criteria which we have stressed in the interpretation of results and to a lack of consideration of the limiting factors imposed by the peculiarity of the liver itself, and not to a weakness of the test itself. All these difficulties can be avoided if the test is applied early in the course of the jaundice. The recent reports of Schiff and Senior, of Rosenberg²⁵ and of Tunen and Piersol²⁶ confirm this opinion.

A recent experience has indicated a possible explanation for some false positive results. As previously stated the metabolism of galactose is in all likelihood a conversion first to glycogen and then to blood glucose. Blanco,²⁷ Block and Weisz²⁸ and Harding and Grant³ have clearly demonstrated that a rise in blood glucose may follow the administration of galactose. The conversion of galactose to glucose in the diabetic too is indicated by the increased blood glucose found by Roe and Schwartzman⁵ after galactose ingestion. In normal rabbits, Roe and Cowgill¹⁴ found that the fall in blood galactose over a four hour period following this sugar sometimes occurred concomitantly with a gradual steady increase in blood glucose. It appears that the rise in blood glucose following the ingestion of 40 grams of galactose may be sufficient to result in an excretion of glucose in the urine in some cases of impaired kidney tubule absorption (so-called low kidney threshold). That this mechanism may be responsible for a false positive galactose tolerance test is indicated by the following instance. M. G., aged 42, presented a history and other data which appeared to indicate a complete common duct obstruction by a stone, yet the galactose output was 3.4 grams. In the absence of long standing jaundice or marked infection in the biliary tree, it was difficult to reconcile the galactose tolerance with the other findings. After fermentation of the urine, however, it was found that the galactose fraction was not over 2.1 grams, the additional 1.3 grams having been present in the form of glucose. A glucose tolerance test done subsequently on this patient yielded strongly positive urinary reducing reactions even though the peak of the blood sugar curve reached only 148 mg. of glucose per 100 c.c. of blood. We have been thus prompted to add the differential fermentation as a routine in all cases in which the urinary excretion after 40 grams of galactose is over three grams. We now carry out the fermentation test as follows:

A suspension of yeast in water is centrifuged, and the supernatant liquid is discarded. Fresh water is added to the yeast, the two are again mixed, centrifuged and again the supernatant liquid is discarded. At the third washing, the supernatant liquid is tested qualitatively for reducing substances with Benedict's or Fehling's solution. If none is present, the yeast is ready for use. Three or more washings are generally necessary for the preparation. Portions of this packed yeast are then transferred to 50 c.c. of the urine sample, and to 25 c.c. of an approximately 1 per cent solution of glucose. The two are then incubated for 30 minutes at 37° C. and the concentration of sugar again determined. The fermentation of the glucose solution

is included as a control on the activity of the yeast. The concentration of reducing substances remaining in the fermented urine is taken as the measure of the galactose excreted.

SUMMARY

1 The galactose tolerance test may be carried out with a fixed dose of galactose, since the utilization of galactose appears to be independent of age, weight or sex.

2 Because the utilization of galactose by tissues other than the liver is minimal or nil, and because of the absence of a kidney threshold for galactose, the urinary excretion after a standard dose of galactose may be taken as a measure of the carbohydrate function of the liver.

3 The determination of the blood sugar curve after galactose is of no value in measuring the utilization of the sugar, because its conversion to glycogen by the liver may alter the glucose content of the blood during the test. The determination of the blood galactose curve greatly detracts from the value of the test by complicating the technical procedure while adding nothing to the accuracy of the results.

4 *In the clinical application of the test the time at which the test is performed in relation to the time of appearance of the jaundice is of utmost importance.* The test has its greatest value and the results are most reliable when it is performed soon after the appearance of the jaundice. The longer the duration of the jaundice before the test is done the more frequently will the results be misleading.

5 Very mild cases of hepato-cellular jaundice may give a negative galactose test throughout the course of the disease. The other clinical and laboratory data will serve to identify this group.

6 The test has its greatest value in the painless jaundice group of middle and later life. If used early and judiciously in this group it will be of immense help in prognosis and will help prevent unnecessary surgery in the hepato-cellular jaundice of those age periods.

7 Because of the possibility of some glucose excretion after the dose of galactose in some disturbed endocrine states [thyroid, adrenal, pituitary, potential or mild unrecognized diabetes, or in cases of impaired renal tubular absorption (so-called low renal threshold)], we feel that differential fermentation of the urine with properly prepared yeast should be made part of the routine technic in all cases in which the excretion of reducing substances in the five hour urine exceeds 3 grams.

NIGHT BLINDNESS AS A CRITERION OF VITAMIN A DEFICIENCY REVIEW OF THE LITERATURE WITH PRELIMINARY OBSERVATIONS OF THE DEGREE AND PREVALENCE OF VITAMIN A DEFICIENCY AMONG ADULTS IN BOTH HEALTH AND DISEASE^{*}

By HAROLD JEGHERS, M D , *Boston, Massachusetts*

IN contrast to the hundreds of papers concerning the experimental, chemical, and pathological aspects of vitamin A deficiency are the small number of clinical studies. Such clinical investigations as are available deal, for the most part, with infants and children, and until recently, the manifestations of deficiency in adults have been overlooked or ignored^{1, 2, 3}

Probably few physicians in this country are aware that there are now available several methods of quantitatively estimating the degree of vitamin A deficiency in humans, and further that some of these methods are simple enough for routine clinical use. Investigations in Europe and this country have shown that our conception of the prevalence of avitaminosis must be revised. In this country, Jeans and Zentmire⁴ and Sandler⁵ have investigated the prevalence of vitamin A deficiency in children. However, there have been no studies on adults using this technic, except by Park,^{6, 7} whose work has appeared since the inception of this investigation.

It is the purpose of this paper to report some observations concerning the degree and prevalence of vitamin A deficiency among a group of supposedly normal adults and also to give some preliminary results obtained by testing persons afflicted with various types of diseases. The important literature dealing with vitamin A deficiency will be briefly reviewed, since much of it is widely scattered and a proper orientation is necessary to understand the significance of the newer developments in this field.

PHYSIOLOGY AND BIOCHEMISTRY OF VITAMIN A

To truly appreciate the clinical manifestations of vitamin A deficiency, it is necessary to know where and in what form the vitamin is found, what happens to it after ingestion, where it is stored in the body and the rôle it plays in conditioning functional activities of humans.

The vitamin A content of our diet comes from two distinct sources, namely alpha, beta, and gamma carotene and cryptoxanthin (grouped under the designation carotene or carotenoid substances for convenience) from the plant kingdom, and true vitamin A from certain animal tissues⁸

^{*} Received for publication October 29, 1936

From the Fifth (Boston University) Medical Service, Boston City Hospital, and The Department of Medicine, Boston University School of Medicine, Boston, Mass.

Aided by a grant from the Committee on Scientific Research of the American Medical Association

Animals and humans are unable to synthesize either carotene or vitamin A in their bodies and must depend on exogenous sources for their supply. The carotenoid substances are synthesized by plants, and from them the animals of both land and water derive their supplies either directly, or indirectly by preying on other animals.⁸

A recent editorial in the *Journal of the American Medical Association*¹⁰ summarizes the differences between carotene and vitamin A as follows: "They are not identical substances: carotene is yellow, whereas vitamin A has little color; vitamin A exhibits an absorption of light of wave length 328 millimicrons, carotene does not, both give a blue color with antimony trichloride but that with vitamin A shows an absorption band of 619 millimicrons, whereas that with carotene absorbs light of wave length 590 millimicrons. Carotene is a crystallizable hydrocarbon with a cyclic structure, related to the terpenes, and the recent evidences indicate that vitamin A is probably a primary alcohol derivative of one half the carotene molecule."

Being fat soluble substances, both carotene and vitamin A are absorbed by the lacteals of the intestine, become intimately associated with the chyle and enter the general circulation through the thoracic duct.¹¹ No change in either substance takes place during the absorbing process. Vitamin A is directly stored in the liver until used by the body. Carotene is changed to vitamin A in the liver by an enzyme called carotenase, one molecule of carotene giving rise to two molecules of vitamin A.¹² The liver also plays an important part in the regulation of the concentration of the vitamin throughout the remainder of the body.⁹ Examination of livers of healthy humans killed by accident, shows that the vitamin A content tends to remain constant within certain limits.¹³ However, when the diet was poor the amount of this vitamin stored in the liver was found to be less than normal.

Rowntree¹⁴ was able to show that even after the ingestion of an excess of the vitamin only 2 to 12 per cent was lost in the feces. Green¹⁵ believes that the urinary excretion does not account for any significant loss and that if taken in excess, the unstored portion of the vitamin is destroyed in the liver or oxidized in the blood stream.

When this vitamin is entirely absent from the diet, experimental work suggests that it takes several weeks or longer to deplete the liver store and cause vitamin A deficiency to become manifest clinically.⁹

Fever,⁸ rapid growth,¹⁰ general infection,¹⁷ elevated basal metabolic rate,¹⁸ and pregnancy¹⁹ all increase the metabolic need for vitamin A. Lack of bile²⁰ or pancreatic secretion,²¹ changes in the gastrointestinal mucosa,⁷ and disturbances of motility of the gastrointestinal tract¹⁷ all prevent or hinder the proper absorption of this vitamin. Liver disease¹⁷ prevents the proper storage of vitamin A as well as the conversion of carotene to vitamin A. Any of these mechanisms can lead to vitamin A deficiency even though the amount of the vitamin in the diet is theoretically adequate.

Both carotene and vitamin A are effective when given parenterally⁹

The functions of vitamin A have not been entirely settled. Its growth promoting and anti xerophthalmic functions are well established⁹. Mendel⁹ is not sure whether it is a 'necessary integral part of structures like the epithelial cells or whether it acts as a catalyst or as a "regulator" of certain cellular functions. The anti-infective nature of this vitamin has been the subject of much controversy. The most reasonable stand is taken by Mendel⁹ who believes "that its influence is felt indirectly in that the vitamin helps to preserve the physiologic integrity of various epithelial structures and thus to maintain the 'first line of defense' against the invasion of bacteria."

It seems to matter little whether the vitamin is present as pure vitamin A or carotene in our food. Cow's milk, human milk, eggs, animal livers, cod-liver oil and cheese all contain adequate amounts of vitamin A. Butter contains both vitamin A and carotene. Spinach, watercress, carrots, green peas, lettuce, oranges and tomatoes are among the better sources of carotene. Storage, bleaching, oxidation and other processes may reduce the vitamin activity of any food⁵.

PATHOLOGY OF VITAMIN A DEFICIENCY

Eusterman and Wilbur²² in their review wisely suggest that a broad view of the pathology of vitamin A deficiency be taken and that attention be not, as in the past, concentrated chiefly on changes in the ocular organs. Wolbach and Howe,^{23, 24} Goldblatt and Benischek²⁵ and many others have shown by experimental studies that specific changes in the tissues in vitamin A deficiency affect primarily the epithelial tissues, and consist of substitution of keratinized stratified squamous epithelium for normal columnar epithelium. Such changes were found in the eyes, para ocular glands, genito-urinary tract, alimentary tract and respiratory tract. Emaciation and atrophy of glandular organs were occasionally found. There is at present question whether or not the central nervous system is involved²⁶.

Pathologic studies of avitaminosis A in human beings, although few in number, have been considered to show lesions identical with those found in experimental rats^{21, 27, 28}. This aspect of the subject has been reviewed recently by Blackfan and Wolbach²¹ and Sweet and K'Ang². To the basic animal work have recently been added the histological studies of the skin lesions in humans²⁹.

Since intact, healthy epithelial membranes, which constitute the first line of defense against bacterial invasion, are destroyed by vitamin A deficiency, secondary infection commonly complicates the more advanced cases and is the cause of most of the deaths².

Blackfan and Wolbach,²¹ in studying humans, were able to show at postmortem examination that often various tissues showed microscopic evidence of vitamin A deficiency even though grossly the organs appeared

normal and during life the patient presented no gross clinical evidence of vitamin deficiency. Since they studied small children or infants, it was impossible to state whether or not hemeralopia existed during life.

These observations are important in that they suggest that mild degrees of vitamin A deficiency (such as can be detected by the photometer) may be associated with microscopic changes in various epithelial tissues throughout the body.

CLINICAL PICTURE OF VITAMIN A DEFICIENCY

It is generally accepted now that in adults and older children, essential hemeralopia (night blindness) is almost always the earliest manifestation of vitamin A deficiency^{1, 2}. In infants and small children this symptom is of course easily overlooked. In contrast to infants, where the disease progresses rapidly, hemeralopia may for many years be the only manifestation in adults^{1, 10}. It is also accepted that even severe degrees of hemeralopia can exist without ophthalmoscopically demonstrable changes in the eye being present^{1, 31}.

As the degree of avitaminosis A progresses gross anatomical changes occur in the eye. Pillat¹² considers dryness of the conjunctiva (xerosis) to be the usual second stage of this disease. Both bulbar and palpebral conjunctivae may be dry and lustreless and contain spots (Bitot's spots) which have the appearance of foam or frost on a window pane. In size the spots may vary from tiny specks to areas large enough to cover the whole scleral area beyond the cornea. They are firmly attached to the conjunctiva and wrinkle peculiarly as the eye-ball is moved. There is lessened secretion of tears due to the inactivity of the para-ocular glands. The process at this stage is reversible under proper therapy. Excellent illustrations of Bitot's spots can be found in the papers by Spence³⁰ and Pillat³³.

Keratomalacia is the last stage of the eye manifestations in adults as well as in infants³². This condition results from corneal softening which allows secondary infection to take place, and often leads to destruction of the eye and blindness. Pigmentation of the conjunctivae, giving the appearance of argyrosis, has been noticed, particularly in the dark skinned races^{33, 34}. Meibomitis, blepharitis, hordeolum and edema and puffiness of the eyelids are common³³. Insensibility of the cornea, almost to complete anesthesia, is frequent³⁵.

By the time the second or xerotic stage in the eye is reached, other manifestations of avitaminosis A are noticed elsewhere in the body. This is, of course, in keeping with the pathological demonstration of widespread metaplasia of epithelial tissues.

Bronchopneumonia, bronchitis, bronchiectasis, infections of the nose and accessory sinuses or hoarseness are commonly seen when xerosis or keratomalacia is present, and indeed one of these complications (especially bronchopneumonia) is a common cause of death in vitamin A deficiency.

Probably next to the eyes, the skin undergoes the most marked and extensive change of all.² Dryness is the most frequent, but least characteristic change. Itching may occur. The most specific cutaneous lesion was described by Frazier and Hu,²⁹ and since repeatedly confirmed^{36, 37} The lesions vary from a slight roughening of the skin to papular cornified lesions surrounding the hair follicles, and are usually more marked over the extensor surfaces of the extremities and over the shoulders. The dry skin results from the deficient function of the sebaceous and sweat glands. Numerous comedones on the face are frequent. Hair may become dry, coarse and brittle, and fall out. In infants and small children the skin manifestations are limited to dryness, scaliness and shriveling, and only rarely show the keratinized plugs in the hair follicles. Frazier²⁹ and Mackay³⁸ believe that skin lesions may exist before xerosis is present and are a valuable sign of avitaminosis A when the presence of hemeralopia cannot be ascertained (as in children or when a photometer is not available for testing adults).

Loss of weight, weakness, genito-urinary infections,² diarrhea² and mild anemia³⁹ are less frequent and less characteristic manifestations. The relationship in humans between the lack of vitamin A and the formation of kidney stones is still controversial,⁴⁰ as is that between avitaminosis A and the common cold.⁴¹ Laboratory studies yield variable results.² A temperature of 101° to 104° F (aside from that due to infection) may be present in the second and third stages in adults, and disappears in a few days under therapy.³³ A detailed discussion of the clinical picture can be found in the papers by Eusterman and Wilbur,²² Blackfan and Wolbach,²¹ Sweet² and Mackay.³⁸

It should be appreciated that manifestations of avitaminosis A (other than hemeralopia), while rare in this country, continue to be the subject of periodic reports.^{42, 43, 44, 45} If hemeralopia were searched for, probably most cases of vitamin A deficiency could be diagnosed before any gross changes had taken place.

NIGHT BLINDNESS

Night blindness, often called hemeralopia, *dysaptatio visualis*,⁴⁶ *hesperanopia* (French),⁸² *nyctanopia*,⁸² *nutritional dyskotopia*^{47, 48} or erroneously *nyctalopia*, is the difficulty, and occasionally, inability to adapt the faculty of vision to very faint illumination.

There has been in the past considerable confusion as to the nomenclature of day blindness and night blindness. The terms hemeralopia (literally meaning day sight) and nyctalopia (meaning night sight) have been used interchangeably so often that the best usage of these terms is difficult to decide. Most modern authors and the "Quarterly Cumulative Index Medicus" list night blindness as hemeralopia. Edmund⁴⁶ suggests that the term nyctalopia, be used to designate the condition of being more easily dazzled by light than normally and hemeralopia be used to indicate a reduction of visual function in reduced illumination.

Hemeralopia (night blindness) may develop in many conditions causing changes either in the light-refractive apparatus of the eye or in the light-perceptive apparatus¹. The first group is made up by affections of the cornea, anterior chamber, lens or vitreous humour. Conditions which can cause changes in the light-perceptive apparatus and cause hemeralopia include retinitis, choroiditis, retinitis pigmentosa, detachment of the retina, optic atrophy, optic neuritis, sympathetic ophthalmia, glaucoma, excessive myopia, poisoning (quinine, carbon disulphid, various war gases, etc.) and Oguthis' disease.

Grouped under changes in the light-perceptive apparatus is essential or idiopathic hemeralopia due to vitamin A deficiency. *In this type of hemeralopia, however, there are no ophthalmoscopically demonstrable changes in the eye.*

There is now abundant evidence available to show that in older children and adults, essential hemeralopia is usually the earliest and the most constant manifestation of avitaminosis A,^{1,2} and that it may exist for years without any other sign of the deficiency appearing.³ Only severe degrees of night blindness annoy the patient sufficiently to cause him to seek medical attention.⁴ In this country, such cases are fairly uncommon as compared to the milder to moderate forms of hemeralopia which can be detected only by the methods to be described.⁵ It is only beginning to be appreciated that a mild to moderate degree of night blindness may be present and interfere with the efficacy of dark adaptation and visual acuity in dim illumination without the person being aware of its existence.¹

According to the duplicity theory of vision, the eye has two distinct mechanisms for sight. Photopic vision occurs only with light of moderate or high intensity and is essentially a function of the cones. With this type of vision objects are seen in their true color. Vision under faint illumination (scotopic vision) is mostly peripheral and primarily a function of the rods. If a spectrum of low intensity is viewed with the dark adapted eye it appears as a gray band differing in brightness in different parts. In other words, with dim vision objects are only seen as different intensities of gray. Rod function (scotopic vision) depends upon the metabolism of the phototropic substance known as visual purple (rhodospin) of the retinal rod cells. Since, as it will be shown later, visual purple is formed from vitamin A, it follows that scotopic vision is intimately associated with the available supply of this vitamin. Practically all tests commonly performed on eyes (i.e. visual acuity, depth perception, accommodation, test for color blindness and ocular muscle balance) are conducted in good illumination and therefore depend on cone function. Since cone function does not depend upon a supply of visual purple or vitamin A, we can appreciate how a person may rate 100 per cent in all these tests and still be so night blind as to scarcely be able to get about in dim illumination. Also since none of these tests will detect night blindness, we can appreciate why mild degrees of this condition were readily overlooked in the past. It explains in addition why the special

tests to be discussed later must be utilized in testing for night blindness. It is well known that animals or birds lacking in cones can see only at night (rod vision) and those lacking in rods can see only in bright daylight (cone vision). In the human eye the rods are more numerous at the periphery and sparse about the fovea. This explains why scotopic vision is mostly peripheral. The periphery of the retina is sixty times as sensitive to light as the central parts. The cones on the other hand are more numerous about the fovea and diminish as the periphery is reached. Therefore photopic vision is more acute in the central portion of the eye.⁴⁹

Visual purple (rhodospin) is very sensitive and becomes bleached and inactive when exposed to light (sunlight or artificial light) and rapidly regenerated if an adequate supply of vitamin A is present in the body. The chemical change which takes place during this bleaching of visual purple gives rise in the rods to impulses which are carried by the optic nerve to the brain and result in the registration of sight in terms of light and darkness.

Vitamin A has been shown to be the precursor of visual purple^{50, 51} and the vitamin is present in large amounts in the retina^{52, 53}. A deficient intake of this vitamin causes the body stores to be low and this in turn leads to slow and poor regeneration of visual purple. An inadequate supply of regenerated visual purple causes the retinal rod cells to be less sensitive to light, and this in turn causes poor vision under faint illumination (hemeralopia).

Wald^{52, 54, 55} has done much to clarify the relationship between visual purple and vitamin A, and was able on frogs to work out the following cycle of vitamin A in the eye.

Vitamin A, by means of a thermal reaction, is changed to visual purple which is a conjugated protein. Exposure of visual purple to light causes the purple color to disappear and allows the yellow or orange colors due to retinene (visual yellow) to appear. Visual purple is synthesized in the retina, either by reversion from visual yellow (retinene) or by regeneration from a fresh supply of vitamin A. During this cycle, a certain amount of these substances is lost, necessitating the arrival of a constant supply of vitamin A in the blood stream.

Night blindness (hemeralopia), as a symptom, has been known since the time of the ancient Egyptians and Hippocrates.² Even the beneficial results of liver therapy were described by Paul of Aeginta.⁵⁶ Hemeralopia of a marked degree has been described repeatedly in the literature as occurring in prisoners, inmates of asylums, soldiers in barracks, in religious groups during fasts, in crews of vessels on long voyages, in starving people during famines or long sieges.¹ What was described by the old sailors as moon blindness was undoubtedly night blindness⁵⁶ and the older literature suggests it was as common as scurvy. During the World War, hemeralopia was very common in the soldiers of the Central European Armies, often rendering large groups unfit for night duty.^{1, 57, 58}

It has been shown, in experimental animals⁵¹ as well as in humans,³¹ that hemeralopia becomes much more manifest in vitamin A deficiency after the eye has been exposed to light. A person who remained in a dimly lighted room all day would need but little visual purple to carry on his visual needs, as compared to a person who remained in the sunlight all day. Aykroyd³¹ reports that on the Labrador coast, night blindness was common and severe in those fishermen who were outdoors all day in open boats and either much rarer or milder in those persons who remained indoors and worked at other trades, in spite of the fact that all persons ate the same type of food. Evidence was also presented which showed that no amount of exposure to sunlight could cause hemeralopia to appear if the diet contained a normal supply of vitamin A. Aykroyd³¹ found further that it was the custom among some persons in Newfoundland and Labrador, where severe vitamin A deficiency was common, to wear a bandage over one eye while the other eye was left uncovered in order to see to carry on the day's activities. After dark they would remove the bandage. The eye which had been exposed to the sunlight would be night blind, but the other eye, which had been covered, would not be so severely affected and served them for sight until the next morning, when the procedure was again repeated. Wearing dark glasses during the day time also helped persons with night blindness to have better visual acuity after dark.

As will be shown later, mild to moderate (and occasionally severe) degrees of hemeralopia due to vitamin A deficiency are fairly common among many supposedly healthy adults, both in this country and in Europe. An important conclusion to these studies is that this large group of individuals, without in most cases being aware of it, have vision which while normal in daytime, is inefficient in dim illumination. The degree of this inefficiency would vary, of course, directly with the degree of vitamin A deficiency which was present.

Certain important practical problems dealing with essential hemeralopia in persons who drive automobiles at night, aviators and workers in certain trades, have been discussed in detail elsewhere by Jeghers⁵⁹. Chief among these has been the effect of minor and mild degrees of hemeralopia upon the skill of a person who drives an automobile at night.

Several persons were found who had night blindness severe enough to cause them to complain of difficulty in driving at night for fear of accidents and of being easily dazzled by the lights of oncoming automobiles. Many mild hemeralopics were found who drove automobiles and were unaware of this lowered visual acuity for dim illumination. Where tried, therapy caused complete relief of these symptoms and improvement in the ability to drive at night. In night driving we have what amounts to a perfect experiment to bring out hemeralopic manifestations if vitamin A deficiency exists. The glare from the lights of each oncoming car depletes a fraction of the visual purple. If the person has avitaminosis A, regeneration is slower than normal and not complete at the time. Several hours of night driving could

easily decrease the skill of a vitamin A deficient person to the point where his chance of having an accident would be greatly increased. Being an individual affair, automobile driving at night does not enable one to compare directly his skill with that of a person with normal dark adaptation. Hence, many persons probably accept minor degrees of difficulty in night driving as the usual experience of all drivers.

Park,⁶ Vignalon,⁶⁰ Rollet,⁶¹ Wilbur and Eusterman,¹⁷ and Tilderquist⁶² have all reported instances of hemeralopics who had accidents or marked difficulty in driving automobiles at night, and where vitamin A therapy was tried, all obtained relief. Mason's⁶³ survey shows that in this country a test for essential hemeralopia is not at present required of any candidate for a driver's license.

As defined by Edmund,⁴⁸ nyctalopia signifies the condition of being more easily dazzled by light than normally. In other words, a person with nyctalopia complains of being dazzled by an illumination which has no dazzling effect upon normal persons. While nyctalopia can be due to various eye diseases, Edmund has shown that it is present in many persons with hemeralopia and vitamin A deficiency, and that it will disappear after vitamin therapy. What is commonly known among autoists as "glare blindness" due to exposure to bright lights while driving at night, may be a manifestation of vitamin A deficiency in an as yet undetermined percentage of the cases. An extensive survey of the incidence of hemeralopia and "glare blindness" among automobile drivers is at present under way and will be reported upon later.

It has been amply demonstrated that normal visual acuity, as usually tested, is no guarantee against the presence of night blindness. Frandsen¹ had many hemeralopics with 20/20 day vision who had very poor vision in dim illumination. Likewise, it has been shown that mild to moderate degrees of hemeralopia are accepted as the normal situation, unless skill in performing an act in diminished illumination is compared to the simultaneous performance of a similar act by a person with normal dark adaptation.⁵⁹ For instance, a person with mild vitamin A deficiency will have more difficulty in going from bright daylight into a darkened cinema and find his way to a seat than will a person with a normal supply of vitamin A.

METHODS OF DETECTING VITAMIN A DEFICIENCY

In the past, vitamin A deficiency was not recognized until marked hemeralopia, xerophthalmia or keratomalacia developed. It should again be emphasized that these manifestations represent severe and well advanced degrees of avitaminosis A, and are rare compared to the milder, and often clinically undetectable, degrees of deficiency.

For many years, foreign investigators have been using various types of photometers to measure quantitatively minor to moderate degrees of night blindness.^{1, 57} It was also discovered empirically that hemeralopia not due

to intra-ocular disease would respond to food rich in vitamin A, with a subsidence of the symptoms and a return of the photometer reading to normal^{57, 58} The experimental demonstration by Fridericia and Holm⁵⁰ and Tansley⁵¹ that vitamin A was necessary for regeneration of visual purple, the studies by Holm⁶⁴ by means of a jumping test conducted in a dimly lighted room, that hemeralopia was the first manifestation of vitamin A deficiency in rats, along with the numerous clinical studies showing the relationship between marked hemeralopia, *xerosis conjunctivae* and keralomalacia, and avitaminosis A^{65, 66, 67} led to the logical conclusion that such photometer tests could be used to detect sub-clinical degrees of vitamin A deficiency

In a recent monograph on the subject, Frandsen¹ summarizes the objective data concerning essential hemeralopia as follows "These patients show an *increased minimum light visible* In *reduced illumination* the acuity of vision is lowered, the field of vision for blue in higher degrees of hemeralopia becomes smaller than the field for red Dark scotoma appears at higher clarity than in the case of normal light sense, the adaptation time is prolonged, the power of distinction is lowered—all signs which signify that the range of adaptation is reduced"

One of the following methods listed by Edmund⁶⁸ and Frandsen¹ can be used

Method One

Minimum light visible determination (faintest light which the eye can detect) sometimes together with plotting of adaptation curves

Method Two

Visual field examination at reduced illumination

Method Three

Visual acuity determinations at reduced illumination

Method Four

Examination of distinction power

I The first method involves the use of a photometer Although various types of photometers can be used,^{1, 68} the Birch-Hirschfeld photometer, introduced by Birch-Hirschfeld in 1916,⁵⁷ has been used for clinical studies in Europe,¹ China⁶⁹ and in the United States^{4, 5, 6} with good results In 1934, Jeans and Zentmire introduced in this country the Birch-Hirschfeld photometer as a means of measuring minor degrees of vitamin A deficiency The mechanism and use of this instrument are described later

An American firm has recently perfected a new photometer called the "Bio-Photometer" * (see figure 1) Since it was designed primarily for routine clinical use it will undoubtedly displace many of the more cumbersome photometers now on the market It operates on the principle of measuring the minimum light visible and has the advantages of greater

* The Bio-Photometer is manufactured by the Frober-Faybor Company, Cleveland, Ohio

portability, compactness, and of measuring the minimal light intensity which the eye can see directly in milli-foot candles. This photometer can measure differences of one-millionth of a foot candle of light. This obviates the necessity of standardization of the instrument by the operator and allows readings obtained by one instrument to be compared directly to another. In addition, a standard source of bleach light is provided within the instrument.

Jeans et al.⁸³ have recently given their experience with this photometer and explain the technic of its use. Since readings can be made in a few

FIG 1 The bio-photometer. This instrument is compact, made in portable models, contains a standard light within the instrument for bleaching visual purple and measures the minimal light visible directly in milli-foot candles. (Photograph courtesy of the Frober-Faybor Company, Cleveland, Ohio)

seconds, the adaptation curve in the dark can be plotted instead of merely depending on a reading at the beginning and end of the dark adaptation period, such as in the Birch-Hirschfeld technic. Jeans et al.⁸³ were able to show that the "Bio-Photometer" is more sensitive than the Birch-Hirschfeld and will pick out border line cases of deficiency missed by other methods.

II Visual field determinations serve as the second method of detecting essential hemeralopia and are according to Edmund⁶⁸ accurate and satisfactory for experimental studies but too complicated for routine use. *It is important that the test be done under reduced illumination and standard-*

ized on subjects with no intraocular disease and ingesting an adequate supply of vitamin A, if one wishes to detect minor degrees of hemeralopia

Kiang,⁷⁰ studying subjects in China by the perimeter method, found concentric contraction of the visual fields with the blue field smaller than the red. The contraction of the color field was proportional to the severity of the deficiency. Following vitamin A therapy, the visual fields returned to normal size while the blue field became larger than the red.

III The third method, examination of visual acuity at lower illumination, has been employed by a great many authors and gives a good expres-

sion of light sense of the eye, but is not a suitable method for routine clinical examination.¹

IV The fourth method, examination for distinction power, has been used extensively by Edmund,³ Frandsen¹ and others in Denmark. This test requires the use of a set of eight Tscherning photometric glasses combined with Edmund's test charts. (See figure 3.) The photometric glasses are neutral-gray glasses, which absorb the passing light after a logarithmic scale, so that glass number 1 transmits $1/10$ of the light, glass number 2— $1/10^2$, etc., to glass number 8 which transmits $1/10^8$ of the light. The test chart of Edmund consists of gray letters E of varying intensity on a white back-

ground The distinction power is 0.00 when only the darkest letter can be seen, 0.25 if the next darkest E can be seen, etc., increasing by steps of 0.25 until a distinction power of 2.00 is needed to see the faintest letter

The test is conducted by illuminating the test charts with a standard light (details can be found in the monograph by Edmund³) The darkest glasses (number 8) are placed before the subject's eyes After complete

FIG 3 Tacked on the upright board are the nine test charts devised by Edmunds. Each consists of the letter E, gray in color, on a pure white background. The darkest E measures a distinction power of 0.00, the next E measures a distinction power of 0.25, rising in steps of 0.25 until a distinction power of 2.00 is reached for the faintest E. The subject (facing the camera for illustrative purposes) is wearing a special pair of light-proof goggles into which the Tscherning photometric glasses fit. Two of the glasses are lying free on the table, along with an extra pair of goggles. The box on the table contains the complete graded set of Tscherning photometric glasses. The light which illuminates the letters is not shown. The fainter letters E are not visible on this photograph. During the test the subject reads the test charts at a distance of 25 to 50 centimeters.

adaptation in the dark, the subject is shown the illuminated charts. The faintest E which can be seen is the distinction power of the eye for illumination of glass number 8. The subject then closes his eyes and glasses number 7 are substituted for number 8 and the distinction power determined for glass number 7. This is repeated in turn for glasses number 6, 5, 4, 3, 2 and 1. The final reading is made without any glasses before the eyes. These values can be plotted on a graph (see figure 4). A typical normal

and also a curve from a vitamin A deficient person is shown. With vitamin therapy the deficient curve gradually approaches the normal curve. This method has the advantages of being independent of refractive errors, requires no training or intelligence on the part of the subject and the end point can be made objective by turning the E in various directions. The charts are read at a distance of 25 to 50 centimeters and a visual acuity of only 6/36 is needed to see them. This method of testing would be ideal

FIG 4 Typical curves obtained when the power of distinction is plotted for different degrees of dim illumination. With proper vitamin A therapy the deficient curves gradually improve to coincide with the normal curve. The ability to see the darkest letter E is considered a power of distinction of 0.00. A distinction power of 2.00 is needed to see the faintest E. (Modified after Edmund)

for aviators, because using this principle a test for spatial discrimination in dim illumination could be devised.

Edmund³ has shown that the test can also be shortened by using only one determination, usually with the Tscherning photometric glass number 4. This test takes but a few minutes.

The writer is at present conducting an extensive study of vitamin A deficiency comparing Edmund's method and the Bio-Photometer. These results will be published later.

Prior to use of these tests for hemeralopia as a measure of vitamin A deficiency, other laboratory procedures were used for detecting mild degrees

of deficiency of this vitamin. Many workers ^{2, 21, 30} have suggested examining the urine, tracheal secretions, or scrapings from the nasal mucosa or conjunctivae. In any of these, the demonstration of cornified epithelial cells is considered presumptive evidence of avitaminosis A. While useful in the hands of experts, these methods are crude, positive in only the more advanced cases and non quantitative as compared to the visual procedures described.

Carr and Price ⁸⁴ found that antimony trichloride produced a blue color with vitamin A. This test can be used to detect the amount of vitamin A present in the blood stream. Attempts are being made to develop this into a clinical test of vitamin A deficiency ⁸⁵. Further studies may prove this to be a valuable adjunct to study and diagnosis of vitamin A deficiency. It has been shown that the amount of vitamin A in the blood stream varies with the diet, age and infection. What is needed is a series of studies correlating the blood vitamin A and carotene with measurements of night blindness and response of each to proper therapy.

Unfortunately tests for vitamin A deficiency which depend upon some objective manifestation of hemeralopia cannot be satisfactorily used on children under the age of five, due to the lack of intelligent cooperation. This leaves an important group with no test for sub-clinical degrees of vitamin A deficiency.

Quite recently, there appeared the preliminary report of a method which promises to be applicable to this at present undiagnosable group. Fride-richsen and Edmund ⁷¹ were able to work out a method of detecting minor degrees of vitamin A deficiency which is quantitative and could be used to test children even during the first two years of life.

This method depends upon determining the faintest light irritant (minimum reflexible) that is able to provoke an oculomotoric reflex. The magnitude of the required irritant was proved to be fairly constant in normal infants and to depend on the power of adaptation. In infants who are not adapted to darkness a stronger light irritant is required to provoke ocular reflexes than in children adapted to darkness. Measuring the magnitude of the light irritant required in infants who have had the opportunity of adapting themselves to darkness makes it possible to obtain a quantitative idea of the presence of hemeralopia and indirectly the degree of vitamin A deficiency. Follow up studies with this technic ⁸⁸ have shown that vitamin A deficiency is common in infants. Rapid return to a normal minimum reflexible followed vitamin A therapy in those who had low readings.

TECHNIC

The Birch-Hirschfeld photometer * was used in this study (figure 2). The technic of its use and working mechanism are described in detail in the papers by Birch-Hirschfeld ⁵⁷ and Jeans and Zentmire ⁴.

* The Birch-Hirschfeld Photometer was of Zeiss manufacture.

The instrument consists essentially of a metal tube with a light of constant illumination at one end and an iris diaphragm at the other end. This diaphragm allows the aperture to vary from two to 20 millimeters in 10 separate steps. A metal disc containing five holes punched out in the five point quincunx of the throw dice is placed before the diaphragm. In front of the disc slides a Goldberg wedge. This wedge is essentially a glass slide of 13 different opacities, ranging from complete transmission of light at the left end and zero transmission of light at the right end. Various combinations of the 10 diaphragmatic apertures and the 13 different degrees of opacities on the wedge give over 100 finely graduated steps of light intensity.

A light proof dark closet was prepared on each of two wards, with one wall painted white to facilitate bright illumination. The subject was seated facing the white wall in a position similar to that used by Jeans and Zentmire⁴ with the eyes 60 centimeters from the photometer scale and 100 centimeters from the wall.

After exposure of the eyes for five minutes to the indirect light from a 200 watt electric bulb which shines on the white wall (to use up visual purple), the room was made completely dark and an initial reading was taken of the faintest light which the subject was able to see (minimum light visible).

The two holes on the left of the disc, the center hole and the two holes on the right side of the disc were each covered by a different opacity on the Goldberg wedge. In closing the diaphragm the holes on the right disappeared first, then the center hole and finally the left two holes. The point at which the right hand holes disappeared and the center and left hand holes were just visible was recorded as the end point. It is best to begin with a wedge opacity reading of three. If the light from the two millimeter aperture of the diaphragm can be seen as described above, then the wedge opacity is set at four, the diaphragm opened to 20 millimeters and reduced step by step. If, however, on the first wedge opacity tried, the light from the 20 millimeter aperture is not seen, a less opaque wedge setting is used and the process is repeated until the proper arrangement of the lights is finally read.

The eyes were then allowed to accommodate in total darkness for 10 minutes and the reading on the photometer repeated. As the visual purple regenerates fainter and fainter light intensities can be detected. The regeneration time period must be kept constant and timed with an alarm which rings a bell. It is important that during this period no lights of any kind be used in the room.

For this reason it is necessary to memorize the clicks as the wedge and diaphragm position are shifted so that the final reading can be obtained in complete darkness. This is readily accomplished after a short period of practice.

Each reading consists of the wedge position—varying from zero (no opacity) to 13 (complete opacity) and the iris diaphragm aperture varying from two millimeters to 20 millimeters in steps of two millimeters.

The entire procedure takes less than 20 minutes. The photometer, before being used, must be standardized on a group of healthy adults who have taken vitamin A concentrate for several weeks or have had an adequate diet for several months, as well as being free of any intra-ocular disease. In performing the test, a few subjects were troubled with "after images" and were not sure of the end point. This was particularly apt to happen if a long time was taken to reach the proper wedge opacity for the final aperture reading. Skill in handling the photometer and alert cooperation on the part of the subject will minimize this difficulty. Also covering the photometer scale for 10 to 20 seconds to rest the subject's eyes and repeating the reading usually enabled a satisfactory end point to be reached. Those persons who wore glasses were asked to do so during the test. However, this

is not absolutely necessary since Frandsen¹ was able to show that minor refractive errors played no part in causing hemeralopia

It is important to be sure that no intra-ocular condition is present which can cause night blindness, before assigning the lowered photometer readings to vitamin A deficiency

Edmund³ and Frandsen¹ have shown that familiarity with this general method (by repeated trials) did not change the reading of distinction power obtained. In the present series, repeated tests at monthly intervals on several subjects and often by different operators gave essentially the same reading

RESULTS AND DISCUSSION

A total of 274 satisfactory photometer tests were performed. The results are summarized in table 1. The subjects were divided into three groups as follows

Group I Consisted of 22 physicians who ate in the doctors' dining room at the Boston City Hospital

Group II Consisted of 149 subjects comprising WPA employees, medical students, technicians and graduate nurses

Group III Consisted of 103 ambulatory patients. Tests in this group were usually made shortly before discharge

TABLE I
Summary of 274 Photometer Tests for Vitamin A Deficiency

Group	Subject		Normal	Mild	Moderate	Severe	Total
Group One	House Officers	Number	20	2	0	0	22
		Percentage	91	9	0	0	
Group Two	WPA Workers Medical Students Technicians Graduate Nurses	Number	98	42	7	2	149
		Percentage	65.8	28.2	4.6	1.4	
Group Three	Ambulatory Patients	Number	34	43	18	8	103
		Percentage	33.0	41.7	17.6	7.7	

Because of the excellent cooperation, reliable dietary history and the uniform nature of their diet, the members of group one were considered the control group. They were all healthy males varying from 24 to 35 years of age and free of serious intra-ocular disease.

The meals served in the doctors' dining room contained a varied and abundant supply of both vitamin A and carotene. Butter, milk and cream, in unlimited amounts, were served at every meal, eggs five times per week, cheese once per week, liver once per week, whipped cream on desserts weekly,

ice cream three times weekly, and pigmented (yellow or green) vegetables and fruit daily and often at each meal. From a theoretical consideration such a diet supplies more than the minimum amount of the vitamin needed.

With two exceptions, the photometer reading of each person in this group fell into a narrow range which was considered as normal. Each initial reading (after the five minute exposure to bright light) varied from wedge opacity four with a diaphragm aperture of 10 millimeters or less to a wedge opacity of five with a diaphragm aperture of 10 to 20 millimeters. After the 10 minute dark adaptation period, all readings were from the opacity six of the wedge with a small diaphragm aperture up to a wedge opacity seven with a large diaphragm aperture.

Several subjects took carotene daily, in addition to their diet, with no change in the photometer reading. This is in agreement with the work of Frandsen¹ who found that larger supplies of vitamin A than the body needs did not improve the visual acuity for dim vision once it reached a normal level. Repeated tests on a few of the subjects by different operators gave essentially the same photometer readings.

The two doctors in this group who failed to have a normal photometer reading fell into the mildly deficient group. One was trying to reduce weight and had deliberately avoided foods rich in vitamin A. The other had many food dislikes which caused him to avoid certain foods rich in vitamin A.

It was decided that any reading through wedge opacity four or five at the initial reading, and through wedge opacity six or seven after the 10 minute period would be considered as falling into the normal range and that person to be free from vitamin A deficiency. Table 2 contains representative photometer readings of persons who were considered to be receiving an adequate supply of vitamin A in their diet. Mild deficiency was

TABLE II

Representative Photometer Readings Obtained on Persons Receiving an Adequate Supply of Vitamin A

considered to be present when the initial reading was through wedge opacity three and final 10 minute reading through wedge opacity five, and moderate deficiency when the initial reading was through wedge opacity two and the final reading through wedge opacity three or four. Severe deficiency was considered to be present if the wedge opacities readings were less than the moderately deficient group.

It should be appreciated at this point that moderate and severe deficiency by this classification does not mean that the person has xerophthalmia or keratomalacia, but that they represent different degrees of hemeralopia. *Those falling into the severe deficiency group (as classified on the basis of this photometer test) represent the instances of vitamin A deficiency which are on the borderline of being detected by the usual clinical signs and symptoms*

Group two consisted of 149 subjects including WPA employees, medical students, technicians, and graduate nurses. All members of this group were healthy in the sense that they worked daily and had no specific complaints or diseases. Many of the WPA workers and medical students lived on surprisingly small incomes.

Compared to the control doctor group (with their adequate diet) the results here were entirely different, and probably representative of the general populace of poor financial circumstances.

Of 149 subjects tested, 98 (65.8 per cent) fell into the normal group (table 1). Of the rest, 42 (28.2 per cent) were mildly deficient in vitamin A, seven (4.6 per cent) moderately deficient, while two (1.4 per cent) were severely deficient.

Careful questioning of persons in the moderate or severe deficiency groups would often elicit complaints of some difficulty in vision in faint illumination. Several complained of difficulty in finding their way to a seat in a darkened cinema, trouble in driving an automobile at night or of being abnormally sensitive at night to glaring lights.

A study of the dietary habits of this group was interesting. The reasons for deficiency could usually be assigned to one of several obvious reasons. The financial reason was probably most important. A survey of the diet, consumed by control group one, which was shown to be adequate in vitamin A content, includes many expensive food substances. The best sources of vitamin A, such as butter, liver, cream, eggs, cheese and pigmented vegetables and fruits are distinctly expensive items. Persons who are forced to live on a frugal budget, whether they live at home or particularly if they eat in restaurants, can easily become deficient in vitamin A.

Peculiarities in food habits which cause foods rich in vitamin A or carotenoid substances to be avoided or disliked were responsible for several mild and moderate instances of deficiency. Another interesting group comprised those few persons (usually women) who because they feared obesity or were trying to reduce avoided many of the foods rich in vitamin A. The literature is replete with many papers emphasizing that a poorly

chosen reducing diet may cause any of several different deficiency syndromes. Vitamin A deficiency is no exception to this well known clinical observation. Such evidence indicates strongly the need for competent medical advice in the planning and supervision of any reducing regime.

Results secured by other workers, testing supposedly normal persons for vitamin A deficiency, can be compared to the results obtained in this group.

Jeans and Zentmire⁷² tested 404 children, ages ranging from six to 15 years, selected at random at four different places throughout the state of Iowa. Evidence of vitamin A deficiency was found in 26 per cent of the rural group and 53 per cent of the village group. In an urban group the proportion of deficiency for the higher economic level was 56 per cent, for a middle level 63 per cent and for a low economic level 79 per cent. The low figure for the rural district can be accounted for by the abundance of dairy and vegetable products in the diet of the average farmer. Where tested, 95 per cent of the deficient persons had a return of the photometer reading to normal and disappearance of the deficiency, following oral ingestion of either vitamin A or carotene concentrates. Sandler⁵ in studying a group of children living in an orphanage obtained results similar to the above.

Frandsen¹ and Edmund³ have published extensive studies on this subject and have tested many hundreds of subjects, including both children and adults. These investigators found that the percentage of deficiency for vitamin A varied for each group tested. In one group, 65 per cent of apparently healthy school children from Copenhagen were found to show deficiency. Children from orphanages were deficient in an even greater percentage of cases. Of groups of adults tested, the percentage of deficiency varied considerably from low to very high figures, in one instance reaching 90 per cent. Diet and economic conditions were the important factors in determining the degree of deficiency.

Park^{6,7} in testing groups of adults for vitamin A deficiency by the photometer method found it to be present in percentages comparable to those obtained by Frandsen¹ and Jeans and Zentmire⁷² for children. The rural group showed much less deficiency than the urban group. Women trying to reduce weight and persons who ate irregularly or improperly in restaurants were commonly found to be deficient. Park was able to cause the photometer reading to return to normal in practically every instance in a group of deficient persons who were given carotene orally.

These studies conducted in widely scattered locations (Denmark, Iowa, Chicago, Oklahoma and Boston) suggest the need for revision of our current conceptions of the prevalence of vitamin A deficiency which are based upon the old viewpoint, that marked hemeralopia, xerophthalmia or keratomalacia must be present before this diagnosis can be made. Hess and Kirby⁷³ in 1933, sent questionnaires to 50 leading ophthalmologists in this country and found that but few cases of severe night blindness or keratomalacia were observed. On the other hand evidence is accumulating to suggest that even clinically detectable night blindness is by no means rare if one carefully questions those persons whose photometer readings show marked impairment of dark adaptation. In the present series, several persons with such readings complained of difficulties referable to night blindness. Park⁶ found 12 persons who complained of night blindness. One can conclude that clinically detectable vitamin A deficiency, while un-

common, is not as rare as formerly believed. However, the evidence already available indicates strongly that sub-clinical degrees of vitamin A deficiency are very common.

This raises the question of the adequacy of the average American diet in regard to the entire vitamin content. McLester,⁷⁴ in discussing general malnutrition, points out that man's diet is seldom faulty in respect to one factor alone. Editorially, the *Journal of the American Medical Association*⁷⁵ comments: "The physician is chiefly interested in nutritional failure not because of its relation to scurvy, beri beri or any other well defined disease, but because it produces numberless vague poorly defined states of ill health. To prevent nutritional failure, the diet should be considered as a whole, and all essentials, whether vitamin, protein or mineral, should be accorded equal importance."

A situation, entirely comparable to the sub-clinical type of vitamin A deficiency, exists in this country in regard to vitamin C deficiency. Dall-dorf⁷⁶ remarks that, judged by clinical criteria, scurvy is uncommon in this country. An acquaintance with experimentally produced scurvy, however, indicates that various degrees of deficiency associated with a number of morbid changes can occur without classic symptoms or signs of the disease. Studies with the recently developed capillary fragility test⁷⁷ as a measure of sub-clinical scurvy and the direct determination of the amount of ascorbic acid in the blood plasma⁷⁸ suggest that sub-clinical degrees of scurvy are common.

Recent development of quantitative methods of determining other vitamin deficiencies has made the subject of sub-clinical deficiencies a practical and not a theoretical concept^{86, 87}. That sub-clinical degrees of deficiency for any or all of the vitamins exists seems very likely. The entire subject seems worthy of much consideration, and the future may change our present concept of what constitutes an adequate diet for the American people.

Group three comprised 103 ambulatory patients convalescing from the usual run of diseases which one finds on a general medical ward. No very sick or bed-ridden patients were tested, because the subject had to be well enough to walk to the dark room, sit on a stool for 20 minutes and otherwise cooperate in the test. With about a dozen exceptions, the tests were performed shortly before discharge of the patient. Patients with liver and gastrointestinal diseases were tested on admission if they were able to walk to the dark room. An ophthalmoscopic examination was done on each of these patients and only those with normal fundi and clear cornea and lens were used. It was found that cataracts, glaucoma, corneal opacities and various types of retinitis caused low photometer readings.

Thirty-four (33 per cent) of those tested showed no deficiency. While group three is small, they represented, on the whole, those with less serious illnesses, often of short duration.

Forty-three (41.7 per cent) were found to be mildly deficient in vitamin

A, 18 (17.6 per cent) moderately deficient, and eight (7.7 per cent) severely deficient

The sharp increase in the percentage of moderately and severely deficient persons in this group as compared to groups one and two can be explained as follows

(1) The persons in this group belong for the most part in the lower economic level

(2) Many had diseases which caused anorexia, vomiting, diarrhea or otherwise hindered the proper ingestion and absorption of the vitamin

(3) Many were entirely ignorant of what constituted an adequate diet

(4) Some had fever, infection or other disturbance which increased the metabolic need for vitamin A

(5) Several had liver damage which prevented the proper storage of vitamin A or the conversion of carotene to vitamin A

No attempt will be made to correlate vitamin A deficiency with all the diseases found in this group. The number of persons with each disease studied is too small for analysis. The study of a larger series, utilizing a portable photometer so that readings can be obtained from patients too sick to be moved, is at present under way and will be the subject of a later report. The results given here are really those of convalescent persons, and should not be taken as representative values of disease during its most severe manifestations. Undoubtedly, tests conducted on bed-ridden patients at the height of their illness will show an even greater degree of vitamin A deficiency than was present in members of group three.

Typical photometer readings obtained of persons from both groups two and three, who were considered to be either moderately or severely deficient, are tabulated in table 3. It can be readily seen that the photometer readings of this group are noticeably different from those of the control and mildly deficient group. Several persons in the moderately and severely deficient group had stigmata clinically suggesting vitamin A deficiency (i.e., dry skin, hyperkeratosis follicularis of the skin, dry conjunctivae or the subjective complaint of poor vision in dim illumination). Of the persons who saw the photometer light only through wedge opacity zero, one or two would usually complain of some manifestation of hemeralopia if carefully questioned. However, in most cases the degree of disability was not such as to cause them to seek medical advice specially for that complaint. In a group, at present under study, an attempt is being made to correlate photometer readings with these mild subjective and objective clinical evidences of vitamin A deficiency.

Frandsen¹ noted that persons with hemeralopia (as detected by tests for distinction power) often complained of palpitation, dry skin, dry mucous membranes, changes in sweat secretion, asthenopia, photophobia, *mouches volantes*, while the physical examination occasionally showed changes in the conjunctivae of a mild degree and dryness of the skin. Park⁷ observed

that persons with very low photometer readings showed one or more of the following general lack of vigor, easy fatigability, lack of luster of the cornea, nervous irritability, ptosis of eyelids and various visual difficulties including true night-blindness

These studies serve to indicate that while vitamin A deficiency rarely causes serious trouble, it may interfere with the efficient functioning of the body and cause many vague and annoying disturbances which detract from the desirable vim and vigor of life

VITAMIN A DEFICIENCY DUE TO DISEASE

Evidence of vitamin A deficiency may develop even though the daily intake of the vitamin is theoretically sufficient to supply the needs of the body. Vitamin A and the carotenoid substances must not only enter the body, but must be completely absorbed from the gastrointestinal tract as well as changed and stored in the liver before being ready for use by the body.

On a theoretical basis it can be predicted, and from the literature can be gathered much evidence to show, that vomiting, various types of gastrointestinal and gastro-colic fistulae, changes in the gastrointestinal mucosa, lack of pancreatic secretion and chronic diarrheas can all hinder the proper absorption of vitamin A and carotene^{6, 7, 17, 20, 21}. Evidence is also available

to show that there may be a differential absorption of pure vitamin A and carotene. Under certain conditions one may be absorbed where the other is not¹¹. Where such pathological conditions exist it is necessary to increase the intake of vitamin A many times over normal to compensate for the inefficient absorption.

Three persons who were ambulatory and had diarrhea of at least six months' duration were tested with the photometer. The results are included among the results tabulated in table 3. Two were treated for four weeks with 10,000 units (U S P) of carotene daily with no improvement in the photometer readings. Park⁶ reports that where diarrhea existed in his patients no improvement was noted in the photometer readings if the usual oral dose of carotene was utilized. These results suggest that the dose of vitamin A in the presence of poor absorption must either be increased enormously or some vitamin A preparation given parenterally. Parenteral injections have been shown to be effective both experimentally⁹ and in humans^{1, 79}.

Since the liver serves to store vitamin A, release it according to the body needs and convert carotene to vitamin A, one would expect liver damage to cause vitamin A deficiency. It has long been known that liver disease could cause even clinically detectable vitamin A deficiency^{79, 80}. Examination of livers post-mortem for the vitamin A content showed that livers with diffuse damage, caused by fibrosis, inflammation or tumor, had marked reduction in the amount of vitamin A stored¹³.

Photometer tests, both in the present series and in cases reported by Park⁶ and others,¹¹ show that practically every patient with liver disease gave low readings. Of six persons with liver disease, who were able to be ambulatory, all gave low readings on the Birch-Hirschfeld photometer. The readings of four of these cases are included in table 3. The diagnoses included toxic hepatitis, catarrhal jaundice and portal cirrhosis. Two of these were treated with carotene with little or no change in the photometer reading. One woman with hepatitis took carotene, 20,000 units (U S P) daily, for five weeks. In spite of this large dose, the photometer readings did not improve until the jaundice cleared, when within one week a change was noted. The patient was discharged before the study could be completed. Parenteral injection of vitamin A has been reported as successful in liver disease⁷⁹. Since the liver serves to convert carotene to vitamin A, one would expect on theoretical grounds that vitamin A concentrates would be a better source of vitamin A than carotene. However, no data are available to show this.

Aside from absorption and storage, metabolic changes influence the amount of vitamin A needed by the body. Fever,⁸ infection¹⁷ and pregnancy¹⁹ have all been shown to increase the need for vitamin A. Wendt¹⁸ has shown in experimental animals that the presence in the blood stream of an increased amount of thyroxin diminished the vitamin A reserve. In

addition he was able to show that a high basal metabolic rate in humans increased the need for vitamin A. Not enough data have been collected yet to show what the photometer readings would be in persons with hyperthyroidism.

Park⁶ has noted in his series of cases that persons with fever and infections of various types often had low photometer readings. Edmund¹⁹ believes that pregnant women not only have a greater metabolic need for vitamin A but that gastrointestinal absorption of this vitamin is less efficient during pregnancy.

It is evident from the data already on hand that the subject of vitamin A deficiency in various diseases is extremely important and its significance only beginning to be realized.

RESULTS OF THERAPY OF VITAMIN A DEFICIENCY

Belief in the specificity of essential hemeralopia as a measure of vitamin A deficiency (whether detected clinically or by means of a photometer or other instrument) rests on the prompt disappearance of both the subjective and objective manifestations following vitamin A therapy.

Empirically it has been known since the time of Hippocrates² that certain types of hemeralopia would disappear when treated with liver. However, it remained for Bloch⁸⁰ and Blegvad⁷⁰ to correlate the lack of vitamin with essential hemeralopia, xerophthalmia, xerosis conjunctivae and keratomalacia.

Spence⁸⁰ noted that gross hemeralopia improved in three to five days and entirely disappeared in from seven to ten days when cod-liver oil and butter were given in large amounts. Aykroyd⁸¹ and others^{1, 81} have reported similar results.

Every investigator who has studied vitamin A deficiency by means of a photometer or determination of distinction power has noted a return to normal readings after a period of vitamin A ingestion. Frandsen¹ and Edmund³ used cod-liver or halibut-liver oil concentrates and found that most readings became normal within three weeks. Jeans and Zentmire⁴ used three teaspoonfuls of cod-liver oil daily and found that the recovery period varied from four days to six weeks, with an average of about 12 days. Later these same workers⁷² noted that similar results could also be obtained with either cod-liver concentrates or carotene. Park⁶ used carotene in oil (daily dose equivalent to 15 teaspoonfuls of cod-liver oil) and found that the photometer readings returned to normal in from six to 41 days.

The most striking proof that the vitamin A supply of the body controls the photometer reading and distinction power was presented by Edmund¹⁹. This investigator found that a single intra-muscular injection of a vitamin A preparation (40,000 I U per c c) brought about the disappearance of

hemeralopia and an improvement in the readings in the course of from seven to ten minutes

In the present study, 14 of the persons in group two (healthy active adults) who showed low photometer readings were treated with vitamin concentrates with no change in their diet. Each person received daily a carotene capsule⁷ containing 10,000 U S P units of vitamin A activity. Each person was retested at the end of two, three and four weeks on the therapy. The results are tabulated in table 4. With one exception (where it took one month), the photometer reading returned to the normal range after either two or three weeks. Those with very low photometer readings noted a subjective improvement in the ability to see in the dark. One man believed his furuncles cleared for the first time in years. Several persons thought they had more "pep" than usual. Such subjective improvements are hard to evaluate and must be studied on a larger group with appropriate controls.

Of particular interest were three young women who ate at the same boarding house. All showed low photometer readings. The diet was adequate in calories but poor in vitamin A rich food. With no change in diet, one woman had a normal photometer reading after taking carotene for several weeks, while no change was noted in the others.

The results obtained here, plus data collected from the literature, suggest that 5,000 to 10,000 U S P units of vitamin A, whether taken as cod-liver oil, vitamin A concentrates or carotene, will abolish all subjective and objective evidence of vitamin A deficiency even if the diet remains inadequate. However, if any disturbance is present which increases the metabolic need for vitamin A or hinders the absorption or storage, then far greater doses would be needed. It may also be necessary to resort to parenteral therapy.

Since many of the foods rich in vitamin A are relatively expensive, it is suggested that it would be cheaper in many instances to add some vitamin A preparation to the diet rather than attempt to increase the vitamin intake by adding foods rich in vitamin A. This applies in particular to institutions with limited budgets and persons of poor financial means.

A word of caution concerning the excessive use of carotene would be of value. If carotene is absorbed from the intestinal tract faster than the liver can convert and store it, the surplus may be stored in the body tissues and cause a yellow color (carotinemia) to appear. This condition may resemble jaundice, but is, however, neither a disease nor dangerous, and promptly disappears when the intake of carotene is curtailed. None of the subjects in this study developed carotinemia although carotene of dose 10,000 U S P units was taken daily for periods as long as six weeks. Both Park⁶ and, Sandler⁵ had instances of carotinemia in their series when the dose of carotene was pushed above this level.

* The carotene used in this study was generously supplied by the SMA Corporation of Cleveland, Ohio.

SUMMARY

1 The literature dealing with the physiology, biochemistry, pathology and clinical aspects of vitamin A deficiency is reviewed

2 Night blindness (hemeralopia), in the absence of intra-ocular disease, is the earliest and most constant manifestation of vitamin A deficiency in adults

3 In adults, night blindness may exist for years as the only manifestation of vitamin A deficiency

4 Night blindness is associated with certain objective data which can be measured by means of special procedures. These serve as a quantitative estimate of the degrees of vitamin A deficiency and are particularly valuable in that they can detect deficiency long before it becomes clinically manifest

5 The results of studying 274 adults by means of a Birch-Hirschfeld visual photometer and data collected from the literature show that mild to moderate degrees of vitamin A deficiency are common among many supposedly healthy adults

6 Financial reasons, peculiarities in choice of foods, ignorance of a proper diet and a desire to reduce weight, were among the factors leading to deficiency

7 Vitamin A deficiency may occur even if the amount ingested daily is theoretically adequate if any condition is present which (a) increases the metabolic need for vitamin A (fever, infection, elevated basal metabolic rate, rapid growth and pregnancy), (b) interferes with the proper absorption from the gastrointestinal tract, or (c) interferes with the conversion of carotene or storage of vitamin A in the liver

8 Vitamin A deficiency is probably a constant feature of liver disease, and does not respond to the usual oral doses of vitamin A

CRYSTALLINE INSULIN¹

By JOSEPH H. BARACH, F A C P, *Pittsburgh, Pennsylvania*

It is now 14 years since insulin was made available to the medical profession and the results of a vast experience with its effects are now at hand. About two years ago, a modified insulin, protamine insulin, was offered to the medical profession. One of the most interesting revelations that came with this new insulin was the limitations of the old insulin. When reports began coming in on the new insulin, we came to realize how many insulin-treated diabetics in the hands of highly experienced workers were not under good control at all. This admission should have its sobering influence and its good effects.

At this point, let it be said that the newer insulins are nothing other than the original insulin which has been more or less modified. It is as though the vehicle for insulin has been changed and the new vehicles are such that the insulin molecule which they contain is absorbed gradually, and therefore acts more slowly.

CRYSTALLINE INSULIN

One of these newer insulins is crystalline insulin. Insulin was first crystallized by John Jacob Abel of Johns Hopkins University. It is the purest known form of insulin substance. Chemically, crystalline insulin is a complex protein obtained as the end-product of the bovine pancreas. It is a complex molecule which can be broken down into such amino-acids as lysine, cystine, histidine, arginine, leucine, tyrosine, phenyl-alanine, glutamic acid and proline. While up to the present time no one of these amino-acid fractions or any known combination of them has been found to produce the physiological effect of the whole crystalline insulin molecule, it is said to have been the hope of Abel that this complex molecule might be so altered, or combined in such a way as to leave it unaffected by the gastric and intestinal juices. When that is attained, oral administration of insulin may be realized and a great want will be met. Until that is achieved, insulin must be used by the injection method.

Insulin is an amphoteric substance. It has an iso-electric point and above and below this point there is a zone in which its solubility is variable. Beyond that zone the solubility of insulin is rapid and complete. The upper limits of this zone lie usually at a pH of 6.0 to 6.2. Dr. Melville Sayhoun of Detroit has, however, prepared a new crystalline insulin whose solubility is complete only at a pH of 6.4 to 7.0. Its advantages may be stated in simple terms. An insulin of greater alkalinity is absorbed more slowly by the tissues and blood and this in turn slows down the glycolytic effects of the insulin molecule.

* Received for publication October 8, 1936

This new crystalline insulin was released for clinical study about six months ago and we have been working with it since that time. Throughout our studies with this new preparation, we aimed at determining its clinical value on the basis of its effects in comparison with results already obtainable with standard insulin and protamine insulin.

AIMS IN INSULIN THERAPY

The physician treating a diabetic aims at the avoidance of hyperglycemia and hypoglycemia. He desires to accomplish this with a minimum number of injections, for reasons both of convenience and of economy to the patient. These aims will be attained when we have an insulin that will have a positive effect in lowering the blood sugar and one that will do it without getting beyond our control. The ideal insulin and the ideal dosage should stop short of producing insulin reaction or insulin shock, and its action should continue throughout the entire post-cibal absorptive period.

METHOD OF STUDY

Our patients ordinarily receive a liberal carbohydrate and low fat diet, with a commensurate amount of insulin. The only change that we made in the routine of these patients was to substitute crystalline insulin for the standard or protamine insulin which they had been taking. On the appointed day, hourly blood sugars were taken from 8 a.m. to 9 p.m. and hourly specimens of urine were obtained. In the following charts, the solid line represents the level of blood sugar while on standard insulin, the broken line represents the level of blood sugar after the patient had been taking crystalline insulin for a period of three to 14 days. As nearly as possible, all conditions were made the same for the hospital and ambulatory patients.

GLYCOLYTIC EFFECT OF CRYSTALLINE INSULIN

To what extent crystalline insulin can accomplish this may be seen in the following examples.

Case 1 A diabetic patient was stabilized on diet alone and was nearly sugar normal about the eighth day in the hospital. He had not received insulin. An hourly blood sugar curve was made on the eighth day (chart 1). On the eleventh day, he was given 15 units of crystalline insulin at 8 a.m. and the hourly blood sugar curve repeated. The glycolytic value of the crystalline insulin is reflected in the relative position of the two curves on the chart. A further index of the relative values of these two curves is obtained by adding the milligrams blood sugar of every hour. Without insulin the total value is 3168 mg. On the day crystalline insulin was given, the total value of the curve was 2877 mg. It is very evident that the blood sugar was markedly lower after the crystalline insulin, the first and only dose the patient received. These are advantages in taking a patient having a moderate hyperglycemia and glycosuria. In such a case the work done by the insulin is measured with greater certainty.

A glance at this chart further shows that the immediate effect of crystalline insulin was to lower the blood sugar from 180 mg to 77 mg in three hours. It should also be noted that the blood sugar trend for the following nine hours was kept within bounds and that is important. Had we given this patient a larger dose, we may rightly assume that the blood sugar would have reached lower levels.

Case 2 Mr T had been using standard insulin for three years and was under satisfactory control. With standard insulin the sum total of his hourly blood sugar

CHART 1 Hourly blood sugar curves. Solid line no insulin. Broken line crystalline insulin. Glycosuria depicted in lower curves.

curve was 3512 mg. After he had been on the same dose of crystalline insulin, which was substituted for his regular insulin, for seven days, an hourly curve for that day (chart 2) showed a total of 2660 mg. It will be noted that the fluctuations under crystalline insulin were smaller and the curve was comparatively level. It is interesting to note here that the insulins were given before the evening meal and while his blood sugar was quite high in the morning, it fell progressively during the day, regardless of his breakfast and luncheon having been taken without insulin. In part this may have been due to insulin, his own or that which was given him once daily.

CRYSTALLINE INSULIN SERIES

We repeated these experiments in a group of 21 diabetics, making daily curves while the patient was on standard insulin and again after a period of 3 to 14 days or longer on crystalline insulin. Out of these, we found that 12 patients showed a distinctly lower curve with crystalline insulin, while 9 showed a lower curve with standard insulin. In the 12 cases, crystalline insulin lowered the blood sugar to a greater extent and the entire curve remained at a more even level.

The following charts are typical cases which reacted well with crystalline insulin.

TOTAL EFFECT OF CRYSTALLINE INSULIN

We constructed curves based on the average of blood sugar levels for the entire series of cases, as they were affected by both standard insulin and crystalline insulin (chart 8). In this study, we found that in the entire series of 21 cases, standard insulin kept the blood sugar at a lower level than crystalline insulin for a period of 36 units of time, while the same dosage of crystalline insulin kept the blood sugar at a lower level than the standard insulin did for a period of 125 units of time.

The deduction from these observations leads us to the belief that unit for unit, crystalline insulin accomplishes more than standard insulin.

EFFECT ON URINE SUGAR

Along with the hourly blood sugar, we also obtained hourly specimens of urine in these patients. Charts 1 and 3 are examples of the relative effect of crystalline and standard insulins on the total glucose metabolism. In a way, quantitative glycosuria reflects the glucose utilization even more completely than hourly blood sugars.

DURATION OF EFFECT A SINGLE DOSE

In analyzing our curves, we find a marked difference in the length of time that a single dose of crystalline insulin affects the blood sugar curve in different patients. In the last analysis, this may represent the rate of insulin absorption. In our experience it was evident that in juvenile diabetics, absorption must be more rapid or factors yet unknown are at work.

Our observations reveal that whereas in the middle-aged or older diabetics crystalline insulin seemed to lower the blood sugar progressively for a period of 72 hours, in the young diabetics the downward curve was nearer 42 hours' duration. The cause of this is not always easy to estimate in a patient having three meals daily and more than one dose of insulin per day. Whether this variability in effect is due to rate of absorption or insulin sensitivity and insulin insensitiveness, is an unsettled question.

CRYSTALLINE INSULIN FAILURES

There was one group of five cases in which the crystalline insulin curve was definitely not as good as the regular insulin curve. Of these patients, three were middle-aged diabetics and two were juvenile diabetics. In one of these young diabetics we repeated the experiment and found that standard insulin was better than either crystalline insulin or protamine insulin, as charts 9 and 10 will show.

INSULIN REACTION—SHOCK

In going over the blood sugar curves and histories of the entire series, we found that insulin reactions and shock were four times as frequent in the

CHART 2 Hourly blood sugar curves After 14 days on crystalline insulin, the morning blood sugar was 130 mg

CHART 8 Glycolytic effects of crystalline and standard insulins in 21 cases

CHART 9

CHART 10 In this patient, standard insulin was distinctly more effective than crystalline or protamine insulin

standard insulin periods as in the crystalline insulin periods. It was noteworthy that in crystalline insulin cases, when the blood sugar was in the 50 mg zone at which time reactions usually begin to manifest themselves, these patients failed to show the usual symptoms.

SUMMARY AND CONCLUSIONS

Up to the present time, we have found no disadvantages whatever in the use of crystalline insulin, either in its administration or in its effects. Its sugar reducing value by every means that we could determine was actually greater than regular insulin in 12 out of 21 cases. It was less effective in 9 out of 21 cases. The absorption time of crystalline insulin is longer and its glycolytic effects are of greater duration. Insulin reactions or insulin shock occurred only one-fourth as often as when standard insulin was used. Because of its slower action and lessened tendency to produce shock, larger doses may be used to reduce the number of doses per day.

LOBAR PNEUMONIA, AN ANALYSIS OF 1298 CASES *

By J. FREDERICK PAINTON, M.D., F.A.C.P., and HERBERT J. ULRICH,
M.D., *Buffalo, New York*

It is our purpose to analyze the cases of lobar pneumonia in patients admitted to the Buffalo City Hospital from January 1, 1927, to December 31, 1935. During that period 106,374 patients were admitted to the hospital, and of that number 1298, or 1.2 per cent were considered to have lobar pneumonia. Only those cases were included which represented unquestionably typical lobar pneumonia after critical evaluation of clinical records, radiographic findings and postmortem records. Roentgenograms were made in 40 per cent of the cases in this series, while necropsies were performed on 37 per cent of those patients dying of the disease. Of the 1298 patients, 787 recovered, while 511 died, a mortality of 38.5 per cent. It should be stated that in 32 per cent of the fatal cases, the patients died within 12 hours after admission, while nine were moribund upon arrival. If these patients are excluded, the corrected mortality is 37.8 per cent. Even this figure might be considered excessive by some authorities. However, Cecil¹ in a recent report on the death rate in pneumococcal pneumonia states that the death rate varies considerably with the class of the patient studied, being lowest in private practice, somewhat higher in hospitals treating the better class, and highest in hospitals treating purely indigent cases. Thus, the mortality at the Rockefeller Hospital is 19.5 per cent, and at the Bellevue Hospital 35.8 per cent.†

Despite the fact that pneumonia has dropped from second place in 1900 to sixth in 1934, it is still one of the leading causes of death. Metropolitan Life Insurance statistics² indicate that the 1934 death rate in pneumonia was 79.4 per 100,000 population. According to the New York State Department of Health,³ pneumonia causes more loss of life in that state than any other single communicable disease and is exceeded as a cause of death only by heart disease and cancer. The annual loss of life from this cause in New York State alone is estimated at 12,000.

Mortality varies in some degree from year to year, month to month, and markedly so in respect to age incidence and the type of invading organisms.

This yearly variation with its concomitant mortality is clearly depicted in figure 1 and it is apparent that in the majority of years, the mortality rate paralleled the incidence. During the nine year period the lowest incidence was in 1932, while the highest was in 1929.

* Received for publication September 4, 1936.

From the Medical Service of the Buffalo City Hospital and the Department of Medicine, University of Buffalo.

† The Buffalo City Hospital in many respects resembles the Bellevue Hospital, being a municipal general hospital which receives and treats chiefly indigent patients suffering from all types of disease.

An investigation of the incidence of lobar pneumonia for the same period in Buffalo, N. Y.,⁴ confirmed this observation. At the same time, reports gathered from various cities in the United States by the Metropolitan Life Insurance Company² revealed that this high pneumonia incidence prevailed

FIG 1 Yearly incidence and mortality

throughout the country. It was evident from a study of the yearly snowfall and mean temperatures in Buffalo,⁵ that 1929 was not particularly remarkable from this standpoint. Analysis of typing in the present series

FIG 2 Monthly incidence of pneumonia and mortality For period 1927-1935 inclusive

failed to show any predominant type during that year. No explanation is offered except that the country at large was the victim of a mild epidemic.

It is generally true that lobar pneumonia occurs chiefly during the cold winter months, December through March, but figure 2 indicates quite defi-

nitely that April and May on the average produce approximately as many cases as all of the winter months except March. It is also important to note that though the incidence was lowest in the summer months, the mortality rate in summer was actually higher than in the corresponding winter months. An effort was made to determine if meteorological conditions in any way influenced the incidence of pneumonia. Although no absolute relationship could be traced, the highest incidence peaks occurred during months in which precipitation and snowfall were greatest, and the average mean temperature low. This is shown in figure 3.

FIG 3 Incidence of lobar pneumonia in relation to precipitation, snowfall and mean monthly temperature

SEX

It is generally believed that lobar pneumonia, like most serious diseases, occurs more often in men than in women. In this series of 1298 patients, 969 patients were men and 329 patients were women, a ratio of about three to one (figure 4). The mortality among women was 31.9 per cent, while in the men, the mortality was 41.9 per cent or exactly 10 per cent higher. This greater incidence and the increased death rate in men most likely was based on such factors as occupation with its subsequent exposure, mode of living, and alcoholic indulgence.

COLOR

Negroes in Buffalo comprise 2.4 per cent of the total population. In this series 23.2 per cent of the patients were colored, 2.2 per cent were American Indians, and the remainder, 74.5 per cent, were white people. Despite the fact that colored races are generally much more susceptible to respiratory ailments, including tuberculosis, the mortality was higher in the white patients than that in either the negro or Indian patients. This is graphically shown in figure 4.

FIG. 4. Relationship of color and sex to incidence and mortality.

W—White
C—Colored
R—Indian

M—Male
F—Female

AGE

Figure 5 demonstrates the effect of age upon the incidence and the death rate. It is clear that lobar pneumonia is a very serious disease in infants under one year. As children become older the mortality rate gradually declines until the age period of five to ten is reached when it strikes its lowest ebb (9.5 per cent). From that age until senility, the death rate progressively increases in a direct proportion to the age.

The highest incidence periods seem to lie between 20 and 50. Fifty-three per cent of the patients who developed the disease were within this age period. The single decade showing the highest incidence occurred between the ages of 30 and 40.

SYMPTOMS

The onset of lobar pneumonia is usually described as abrupt. Musser⁶ states that antecedent respiratory infection had occurred in slightly over 40

per cent of the Rockefeller Hospital patients. Sudden onset in 58.1 per cent of our patients was followed by a mortality of 31.7 per cent, while in 41.9 per cent who started gradually the mortality was 29 per cent. If the assumption is true that those patients who experienced a gradual onset were in reality the victims of a previous respiratory infection, it is evident that the so-called common cold was actually the precursor of lobar pneumonia in 42 per cent of the cases. Whether or not the type of onset bore any prognostic relation to the mortality is not demonstrated.

FIG 5 Age incidence and mortality

The common cardinal symptoms were considered, such as cough, pain in the chest, chills, dyspnea, and hemoptysis, along with the complicating symptoms, cyanosis, ileus and hiccough. The relative incidence of the various symptoms is shown graphically in figure 6, together with the mortality of the aforementioned complicating symptoms. Although most textbooks list the chill as the most common characteristic symptom, figure 6 clearly indicates that the dry hacking cough was the most constant symptom in this series. Obviously this symptom, because of its frequent occurrence in practically all respiratory diseases, is not pathognomonic of lobar pneumonia, but combined with the other symptoms shown in the table, produces valuable

clinical leads. Pleural pain, which is generally regarded by pathologists as the result of stretching of adhesions, was the next most common symptom, occurring in 61.1 per cent of the patients, and even though second in frequency was still nearly twice as common as chill. The latter symptom, typical chill, occurred in only 33.2 per cent of the patients although more complained of mild chilly sensations. It is interesting to note that Reginald Fitz,⁷ in Peter Bent Brigham Hospital, found only a slightly higher percentage (37 per cent). While the respiratory rate was increased in practically every instance, some patients complained of marked difficulty in breathing. This dyspnea was present in 22.2 per cent. Hemoptysis, the fifth most common symptom in frequency, occurred in only 21.5 per cent of the patients. It should be mentioned that only manifest bloody sputum was considered hemoptysis, blood-streaked or blood-flecked sputum was excluded.

FIG 6 Incidence of symptoms in lobar pneumonia

Cyanosis, ileus and hiccough, though usually regarded as signs, are included in this discussion as complicating symptoms because the latter two frequently occur late in the course of the disease. Our criterion of cyanosis was definite blueness of the lips, fingernails and face, and did not include transient or mild duskiess. It is apparent from figure 6 that although of rather infrequent occurrence, it was an ominous sign.

Marked abdominal distention as a result of ileus is also a serious complicating symptom. It was found in only 10.1 per cent of the patients but carried with it a mortality of 64 per cent. This symptom is probably an expression of profound toxemia upon the sympathetic nerve endings controlling the small intestine.

Hiccough, a rather rare symptom, occurred in only 2 per cent of the cases with a 20 per cent mortality.

From time immemorial lobar pneumonia has been considered the one disease that terminates abruptly by crisis. Cecil,⁸ on the contrary, feels that the majority of cases decline gradually by lysis. Only 54.5 per cent of our

patients who recovered had a sudden fall in temperature, in the remainder the temperature fell gradually by lysis

At this point it seems advisable to recapitulate with an evaluation of symptoms according to the commonly accepted pathogenesis of the disease. Blake and Cecil⁹ have demonstrated that the primary pathologic process in the development of pneumonia is a penetration of the walls of the larger bronchi by the pneumococci. This process in addition to the tracheo-bronchial infection gives origin to the dry hacking cough which was not only the earliest but the most frequently observed symptom. Following the penetration of the bronchi, the organisms pass along the lymphatics of the fibrous septa in a rapid centrifugal direction until the periphery is attained. In the wake of this process the alveoli are reached and ultimately perforated by the pneumococci. This sequence makes it apparent that the exudative process which results in consolidation really starts at the hilus and proceeds peripherally. At the same time the foregoing statement in a measure explains why pleural pain was the second most common symptom. This conception of the pathogenesis of pneumonia may serve as an explanation for the fact that a chill occasionally is observed after the occurrence of cough and pleural pain, and in this series occurred in only one-third of the patients. Both dyspnea and cyanosis are expressions of anoxemia which many authorities feel is due to fluid on the inside of alveoli preventing the diffusion of gases. It seems likely that dyspnea is the result of a moderate anoxemia, while cyanosis, with a mortality of 77 per cent, is a manifestation of grave oxygen lack.

At the same time, it seems quite apparent that the symptoms should be the earliest manifestation of the pneumonic process and precede the development of outspoken signs of clinical consolidation by a matter of hours varying from 12 to 48. We noted this frequently.

LOBAR INVOLVEMENT

Comparisons were made in this study in an effort to determine the relative incidence and mortality of individual lobar involvement, multi-lobe involvement, and the various frequency of upper and lower lobe solidification. This is clearly portrayed by figure 7. Right-sided involvement, including single and multiple lobe consolidation, occurred in 754 patients (58.1 per cent) with 300 deaths (39.8 per cent). Left-sided lesions, considered in a similar fashion, occurred in 462 patients (35.6 per cent), with 162 deaths (35.1 per cent). It is apparent that lobar pneumonia was much more frequent in the right lung, but the mortality considered as a whole was only slightly higher in this location. A comparison of the frequency of involvement of the upper lobes as opposed to the lower lobes reveals that the right and left upper lobes were individually affected in 18.5 per cent of the patients (mortality 29.6 per cent) while the lower lobes were individually attacked in 48.1 per cent of the patients (mortality 33.8 per cent). This

indicates that individually the right lower and the left lower lobes were attacked $2\frac{1}{2}$ times as often as the upper lobes. The ratio is practically the same as that found by Warr and Alperin¹¹ who reported the lower lobes involved twice as often as the uppers.

Similar comparative studies of lobar involvement with relative frequency and mortality rates are described by many writers. Cecil⁸ found the right side involved 666 times and the left 598 times. In his series, the right lower and the left lower lobes were involved in about equal frequency of all single lobar lesions. Right and left lower lobe consolidation was by far

FIG. 7. Lobar involvement in 1298 cases of lobar pneumonia with percentage of mortality.

Note: Figures in parentheses indicate percentage of incidence of various lobar involvement.

Consolidation is indicated by cross hatching.

- Rt Upper and lower—1 case—0 per cent
- Rt Lung and left upper—2 cases—50 per cent
- Rt Lung and left lower—2 cases—50 per cent
- Rt Upper and middle and left upper—2 cases—100 per cent
- Rt Upper and middle and left lower—1 case—100 per cent
- Rt Upper and lower and left upper—1 case—100 per cent
- Rt Upper and lower and left lower—1 case—100 per cent
- Rt Middle and left lower—2 cases—50 per cent
- Rt Upper and middle and entire left—1 case—100 per cent

the commonest bilobar combination. His conclusions were that the seriousness of the disease varied directly with the number of lobes involved. This is in agreement with McCrae¹⁰ who, quoting statistics from 100 autopsies performed at the Montreal General Hospital, reported right-sided lesions in 51 and left-sided lesions in 32. Both lungs were involved in 17. In 29 cases the entire lung was involved, and in 34 merely the lower lobe was affected. The upper lobes alone were affected 13 times. When double, the lower lobes were usually consolidated together, but in three instances the lower lobe in one lung and the upper lobe in the other were solidified. Only in three were both upper lobes affected.

Just why the lower lobes are more often affected than the upper lobes is speculative. If it is assumed that approximately 40 per cent of the patients developing lobar pneumonia have previous respiratory infection, and that lobar pneumonia, as Coryllos and Birnbaum¹² have shown, is essentially a pneumococcal atelectasis due to a bronchial obstruction from a catarrhal plug, the anatomy of the bronchial tree with the right and left bronchus practically continuous with the main bronchus, makes it appear quite logical that the plug should eventually locate in these lower bronchial passages.

SINGLE LOBAR INVOLVEMENT

In discussing monolobar consolidation, it is apparent from figure 7 that the left lower stood out as the most frequently involved lobe, occurring in slightly more than one-quarter of the cases in the entire series (346 cases). Despite the marked frequency of involvement in this particular lobe the mortality was only 31.2 per cent, considerably less than the adjoining upper lobe or the opposite lower lobe. The next most frequent single lobe affected was the right lower which occurred in 20.5 per cent with a mortality of 37.2 per cent. The right upper lobe was third in frequency with an incidence of 14.3 per cent. The left upper lobe was involved in only 4.2 per cent, but was associated with a high mortality (46.3 per cent). Peculiarly enough, although right-sided lesions are almost twice as frequent as left-sided lesions, and although the middle lobe in many cases is almost an integral part of the right upper, this lobe was involved in only 1.8 per cent with a mortality of 36.4 per cent.

MULTILOBAR AND BILATERAL LOBAR INVOLVEMENT

While Harlow Brooks¹³ concluded from his series of 200 autopsied cases that the extent of lung involvement was but of minor value as a prognostic factor in death in lobar pneumonia, many observers, including the authors, have felt that it is one of the important contributory influences producing a fatal outcome.

The following table tends to corroborate this latter viewpoint, and indicates quite distinctly that mortality in multiple lobar involvement is directly proportionate to the number of lobes involved.

It is interesting to note that pneumonia in more than one lobe occurred

TABLE I
Extent of Lobe Involvement in 1298 Cases

Number of Lobes Involved	Total Cases	Fatal Cases	Per cent Mortality
One	874	286	32.7
Two	286	148	51.7
Three	133	74	55.6
Four	5	3	60.0

in about one-third of the entire series, which is slightly higher than the percentage found by Warr and Alperin¹¹ who found multiple lobar involvement in only one-quarter of their series. These authors also stated the mortality was higher when the disease was bilateral than when two or more lobes of one lung were involved.

J A Ryle¹⁴ of Guys' Hospital, writing on the prognosis of lobar pneumonia, is of the same opinion and lists excessive bilateral involvement as the most serious of unfavorable factors in determining prognosis.

Table 2 substantiates the contention that bilateral involvement materially increases the mortality rate and adds to the seriousness of the prognosis.

TABLE II
Bilateral Bilobar Involvement

Lobes Involved	Total Cases	Fatal Cases	Per cent Mortality
Both lowers	45	27	60.0
Both uppers	6	1	16.5
Left lower and right upper	5	2	40.0
Left upper and right lower	3	3	100.0
Right middle and left lower	2	1	50.0
Total	61	34	Av. 55.7

ALCOHOL

Evidence of alcoholic poisoning, manifested chiefly by delirium tremens, was present in 73 patients (figure 8). All were men and 58, or nearly 80

FIG 8 Per cent of mortality in alcoholics and luetics as compared to non-alcoholics and non-luetics

per cent, were white. Fifty-three patients died with a resultant mortality of 72.6 per cent. This mortality is almost double that of the non-alcoholic patients. One might expect a higher percentage of alcoholic patients in a large series such as this, but it should be remembered Harlow Brooks¹³ found histories of alcoholism in only five of his 200 postmortem cases. Undoubtedly there are many more patients who were alcoholics of some degree but were not the severe chronic drinkers who might be expected to develop delirium tremens.

Some observers have felt that chronic alcoholism predisposes to certain lobe involvement. In the present series 22 per cent of the total number of alcoholics developed a right lower lobe pneumonia, while in 18 per cent it was in the left lower lobe. This is interesting as left lower lobe pneumonia occurred in 27 per cent of the total number of patients, while right lower lobe consolidation occurred in 21 per cent of the total number. Although the percentage difference is relatively small, it seems that alcoholics developed processes in the right lower lobe more often than in any other single lobe. No explanation is offered for this coincidental finding.

RELATIONSHIP TO SYPHILIS

Of our 1298 patients, 167 or 12.8 per cent had a positive Wassermann reaction, and of this number, 76 died and 91 recovered, a mortality of 45.5 per cent. This figure is 7 per cent higher than the mortality for the whole series or for the non-luetic group (see figure 8). Seventy-two (43.1 per cent) patients were white, 93 (55.7 per cent) were colored, and two (1.2 per cent) were Indians. The large number of colored patients does not explain this increased mortality as it was shown in figure 4 that the mortality actually is higher in the white race.

It was also thought that possibly fatalities occurred here because of increased age and the presence of late cardiovascular lues. Investigation revealed that these fatal cases were quite evenly distributed throughout the age groups. Only four of the fatal cases showed gross luetic meso-aortitis on postmortem examination. The relationship to typing was inconclusive.

Again a survey of various lobar involvements was undertaken in the 167 patients with lobar pneumonia and syphilis to establish whether any particular lobar predilection existed. The lower lobes were attacked in 41 per cent of the cases, the uppers in only 16.2 per cent, and the middle lobe in only 1.8 per cent. The right lower and left lower lobes were involved almost equally.

The problem of delayed resolution or unresolved pneumonia was also considered in its relationship to syphilis. This complication was relatively uncommon in this series as it occurred in only 27 patients (1.8 per cent). Of these, only four (14.8 per cent) had a positive Wassermann test. These observations are essentially the same as those made by Weinstein and Goodman¹⁵ (Johns Hopkins Hospital) who considered that delay in resolution

TABLE III

of the pneumonic process occurred almost as frequently in the non-syphilitics as in the syphilitics

LEUKOCYTE COUNT

The total leukocyte count has long been regarded as an index to prognosis in lobar pneumonia. It is usually conceded that a good leukocytic response indicates that the patient's fighting forces are mobilized to combat the invader. Total leukocyte studies were made on slightly more than 70 per cent of the patients in the present analysis. Figure 9 demonstrates quite clearly that the optimum total leukocyte count to ensure a good prognosis lies between 30,000 and 40,000. It is also evident that as the total leukocyte

FIG 9 Total leukocyte count in thousands

count decreases from 10,000 downward, the mortality increases in a direct proportion. This is to be expected because diminished resisting forces permit the infection to overwhelm the patient. At the same time, as the total count increases over 50,000, the mortality rate progressively increases. This might be explained by the probability that even though the bone marrow was actively responding to the infection, the toxemia was so profound that death ensued as a result of its degenerating effect upon the heart, higher brain centers and periphero-vasomotor nerve endings.

During the past few years considerable attention has been directed to the differential count as advocated by Schilling. It is generally accepted that the so-called "shift to the left" with an increasing output of young forms indicates a doubtful prognosis. In this survey, total polymorphonuclear leukocyte counts were analyzed, without deriving evidence therefrom,

Schilling counts were performed only during the years 1934 and 1935 so that conclusions are unwarranted at this time

TYPING

The type of pneumococcus was ascertained in about one-quarter, 313, of these patients. This rather small number was due to the fact that the procedure was relatively difficult and expensive during the years preceding 1934, but with the advent of the Neufeld method in 1935, this difficulty has obviously been overcome. However, it is interesting to note (figure 10) that

Fig 10 Typing and percentage of mortality

FIG 11 Relationship of age incidence to type

the incidence is greatest of types I and IV and lowest of type III. At the same time, the mortality rate of type III was approximately twice that of any of the other types, or equivalent to the mortality of any two other types. These observations are not new and have been previously stated by Cecil.⁸

and other authors. It also can be seen from figure 2 that type I and to some extent type II were most common in the patients under 40, while type III occurred more frequently than any other type in patients over 40. This partially accounts for its high mortality rate and also for its relatively low incidence.

It also will be seen from table 3 that type I was the most frequent producer of complications, particularly empyema. On the contrary, type III seldom or rarely produced complications. This paucity was probably related to the fact that nearly 60 per cent of these patients died in the acute phase of the disease before complications usually occur.

COMPLICATIONS

Empyema, in our experience, was the most common complication. It is to be remembered that empyema is always a complication and never a sequel. One hundred and twenty patients (93 per cent) developed pus in the pleural space. This high incidence requires a few words of explanation. In 69 patients (57.5 per cent) the diagnosis of empyema was tentatively made by clinical examination and confirmed by paracentesis. Of these, 46 recovered and 23 died (mortality rate 33.3 per cent). In 13 of the other 51 cases diagnosed at autopsy, there was a rather massive empyema, while in 38 there was present only a purulent exudate on the pleura. The latter finding was designated fibrino-purulent pleurisy, which may be classified as empyema because this type of pleuritis is in reality a localized or loculated empyema. Therefore, in 82 patients there were rather large collections of pus in the pleural space, while 38 others merely developed a purulent appearance of the pleura itself. Many writers feel that if all fatal cases of pneumonia were autopsied, the recognized percentage of empyema would be considerably higher, and it appears that this series supports that viewpoint. However, if the cases showing only fibrinopurulent pleurisy were excluded, the incidence of empyema is 6.3 per cent, which is approximately the percentage found by Cecil⁸ and his co-workers. McCrae¹⁰ basing his statistics on the Johns Hopkin's series, found only 3.6 per cent, while Musser⁶ estimates the incidence as being between 3 and 5 per cent. Warr and Alperin,¹¹ in their large series of 2,039 cases, found an empyema incidence of only 2.6 per cent. It is quite likely that 7 or 8 per cent would be a more accurate figure if all fatal cases of lobar pneumonia were investigated post mortem. Then, too, a great deal depends on whether one is to include rather minute collections of pus in the pleural space as empyema. The mortality rate in empyema in this series was 62 per cent.

Pleural effusion was the second most frequent complication, occurring in 62 patients (4.8 per cent). This figure was considerably higher than that found by Warr and Alperin,¹¹ who recorded only eight pleural effusions in 2,039 lobar pneumonias. Joules¹⁶ reported only five effusions in his series of 496 cases. Both of these figures seem low, if it is borne in mind

that in our series only 22 of the 62 effusions were discovered by postmortem examinations. The remaining 40 diagnoses of pleural effusion were made by clinical examination, roentgenographic studies and confirmed by paracentesis. In all probability most lobar pneumonia is accompanied by slight pleural effusions which are not diagnosed due to lack of sufficient quantity or hesitancy and fear of aspiration.

Next in frequency was otitis media. This complication occurred in 48 patients (3.6 per cent). It was by far the major complication in childhood. Forty-two of the 48 cases occurred under the age of 10. This complication can be considered relatively mild in severity as the mortality was only 8 per cent, or less than the general mortality for the age group from 1 to 10 years.

Chronic fibrous pleurisy also was a frequent complication but it is such a natural pathological sequela to the pneumonic process that further discussion is unnecessary.

Pericarditis was next in frequency occurring in 28 patients (2.1 per cent). The mortality was 85.7 per cent, making this complication one of the gravest. The majority of cases occurred in left-sided lesions which was to be expected inasmuch as pleuritis, pleuro-pericarditis and visceral pericarditis is the usual pathologic sequence.

Unresolved pneumonia or delayed resolution occurred in only 1.8 per cent of the patients. The relationship to syphilis has been discussed. Tuberculosis has been thought to be responsible for many unresolved processes, but in this survey positive evidence of superimposed tuberculosis was rare, as will be brought out later.

Lung abscess was also a relatively rare sequel, developing in only 16 patients (1.2 per cent). This incidence was slightly higher than the Bellevue series of 2122 cases, where only 9 cases were observed. The mortality was exceedingly high, ending fatally in 11 (69 per cent).

Meningitis, the most severe of all complications or sequelae, occurred in 13 patients (1 per cent) terminating fatally in all cases. This outcome must be expected as meningeal involvement is practically always the result of an overwhelming pneumococcal septicemia.

Other complications, such as bronchiectasis, tuberculosis, jaundice and peritonitis, occurred rather infrequently. Bronchiectasis was present in 14 cases (1.8 per cent), 12 of which were discovered post mortem. Apparently it is extremely rare in patients recovering from the disease. Ten patients subsequently developed tuberculosis. It is, therefore, suggested that series showing a higher incidence of tuberculosis possibly include acute pneumonic forms of tuberculosis. Jaundice also occurred in 10 cases with a mortality of 70 per cent. The mechanism of jaundice in lobar pneumonia is rather obscure. Some observers feel that it is chiefly hemolytic, while others attribute it to parenchymatous hepatic degeneration. It is probably a combination of the two processes and in either event is expressive of profound toxemia and warrants a poor prognosis.

Fatal peritonitis occurred in 3 cases and obviously rates in the same category as meningitis as a complication which foretells a fatal termination

The other complications tabulated were so rarely observed that discussion is of little consequence

TREATMENT

The problem of evaluating treatment was attacked with some trepidation. Lobar pneumonia, like many other diseases, has run the gamut of therapy, but the consensus of modern authorities resolves the treatment into oxygen and specific serum when indicated. In this series an attempt has been made to draw some conclusions from the various drugs and therapeutic measures used in the past nine years (figure 12)

FIG 12 Therapy of lobar pneumonia with mortality

The first drug considered was digitalis. This was used in 557 patients with a mortality of approximately 50 per cent. The majority of those who received digitalis entered the hospital during the years 1927 to 1930. All were digitalized routinely. During the past few years, Cohn and Lewis,¹⁷ working at the Rockefeller Institute, have shown that the mortality is actually higher in the digitalis-treated groups. Inasmuch as the mortality in our patients treated with digitalis was nearly 50 per cent, this conclusion seems to be well-founded. Since 1930, digitalis has been used in pneumonia

cases only when such indications as grave cardiac irregularities, auricular fibrillation or congestive failure developed.

The second type of therapy investigated was the use of alcohol in the form of whiskey. This drug was largely used by our medical forefathers and is still used routinely by many physicians today. In 320 patients treated with routine doses of whiskey the mortality was 45 per cent, or 7 per cent higher than the general mortality. This drug, like digitals, has also been discontinued during the past few years and is now reserved specifically for the chronic alcoholic who, in the face of pneumonia, may develop delirium tremens if it is omitted.

Oxygen, the third most commonly employed therapeutic measure, was administered to 149 patients with a mortality of approximately 60 per cent. To the casual observer, this high mortality might be interpreted as minimizing the value of this form of therapy. Some explanation is obviously necessary. Most of the patients who received oxygen were cases showing marked cyanosis, dyspnea or grave circulatory failure. In other words, the majority of these cases probably would have ended fatally whether or not oxygen were used. It should also be stated that the majority of these patients received oxygen by means of the mask, which is now known to be the least effective method of administration. The cases treated in this fashion obviously occurred in the days prior to the use of nasal catheter or the development of oxygen tents and oxygen chambers. Only a few of the patients were given oxygen early in the course of their disease. There is no doubt in our minds that early oxygen therapy, given by the proper methods, is a valuable therapeutic agent.

Glucose (20 per cent dextrose) was given intravenously to 121 patients, and was followed by a 60 per cent mortality. The same applies to glucose as applied to oxygen, namely, that this drug was also used in cases of evident circulatory failure where an unfavorable outcome was anticipated. Even with this high mortality, we believe that the use of this drug intravenously often turns the tide in a favorable direction.

The last form of therapy investigated has been listed under the general term of "supportive treatment." By this term is meant the use of any drug, which can be employed to support the patient in a general way. The judicious use of morphine, codeine, caffeine sodium benzoate, salicylates and quinine may be considered under this heading. The latter drug was used in about 90 per cent of the patients treated by so-called "supportive measures." It has a long reputable record in pneumonia therapy. During the past decade, a closely related drug, optochin, has been highly regarded as a pneumococcicidal agent. Inasmuch as no one has proved any deleterious effect, and, as there may be some beneficial result from quinine administration, it has been retained as a routine therapeutic measure. It should also be mentioned that the combating of toxemia through establishing improved water balance by means of forced fluids orally, and saline administered parenterally is also a valuable and important factor included under the term

“supportive measures” Likewise good nursing care must be included under this blanket term The patients treated merely by “supportive” treatment had the lowest mortality, 37.2 per cent

Pneumothorax was used in seven selected cases with only one death This number is too small to draw any conclusions therefrom

Specific type I serum was also used in such a small number of cases that any clinical deductions are unwarranted

SUMMARY AND CONCLUSIONS

An analysis has been made of the records of 1298 patients having lobar pneumonia observed at the Buffalo City Hospital from 1927 to 1935, inclusive

The mortality rate for the entire series was 38.5 per cent

The incidence of lobar pneumonia and the mortality rate varied considerably from year to year

The incidence of lobar pneumonia varied materially from month to month but regardless of whether it occurred in the winter or summer, the mortality was approximately the same

The mortality rate was highest at the extremes of life and lowest between the ages of five and ten From ten years to old age, the mortality was directly proportional to the age

Lobar pneumonia was three times as common in men as in women and the mortality rate was approximately 10 per cent higher

The mortality rate among northern negroes was less than in the white race

The mortality rate in chronic alcoholics was approximately twice that of non-alcoholic patients

The presence of syphilis materially increased the mortality rate, although no relationship was demonstrated between syphilis and delayed resolution

Chill was not as common a symptom as has previously been believed

Lobar pneumonia, involving one or more lobes of the right lung, was one and one-half times as frequent as left-sided involvement Multi-lobar involvement and bilateral involvement add considerably to the mortality rate and the gravity of the prognosis

Leukopenia, and leukocytoses above 50,000 were serious prognostic findings

Type IV pneumonia was the most commonly observed type, while type III was accompanied by the greatest mortality The greatest number of complications was observed in type I, while the least was seen in type III Type III was the most commonly observed type in patients over 40, type I being the preponderant type in adolescence and early life

Empyema, pleural effusion, and otitis media were the most frequent complications in the whole series, while pericarditis, meningitis and peritonitis were the most fatal

The effect of routine therapeutic measures upon the mortality rate was inconclusive

The authors wish to express their appreciation to Dr Carroll J Roberts for his valuable suggestions and criticisms, and to Drs V Boeck, D Levy, and A Cirrincione for their assistance in the compilation of the statistics

FURTHER OBSERVATIONS OF THE HISTIDINE TREATMENT OF PEPTIC ULCER

By ELLIS W WILLHELMY, M D , *Kansas City, Missouri*

IN 1923, Mann and Williamson¹ reported that they were able to produce in dogs subacute and chronic peptic ulcers, quite like those found in man, by diverting to another part of the intestine those secretions of the duodenum which normally neutralize the gastric juice as it leaves the stomach

Aron and Weiss² of Strasbourg repeated and confirmed these studies. They came to the conclusion that these ulcers formed as a result of an amino acid deficiency. On this theory, they gave intramuscular injections of certain amino acids to dogs that had been subjected to the Mann-Williamson technic, and found that daily injections of 5 c c of a solution of 4 per cent histidine and 2 per cent tryptophan would prevent the development of ulcers in the dog. This experimental work was followed by clinical trial in ulcer patients with marked success, according to their report.

In the due course of time following the publication of Aron and Weiss, other encouraging communications on the use of histidine in the treatment of peptic ulcer began to appear in the foreign literature and eventually, largely through the extensive advertising claims of one of our pharmaceutical companies, the physicians of this country were informed of this work and the results reported by European investigators.

The treatment of peptic ulcer constitutes such a major therapeutic problem that any plausible aid that holds the possibility of a cure or the elimination of the usually accepted, protracted routine of bed rest, milk, alkali powders and diet over a period of months, seems to us to be worthy of consideration, so, with this thought in mind, we began to treat a series of peptic ulcer patients with a series of 24 daily intramuscular injections of 5 c c of 4 per cent histidine monohydrochloride †.

Since January 1935, we have treated 42 roentgen-ray proved cases of peptic ulcer. Of these 42 cases, we have been able to carefully follow and recheck closely the clinical and radiographic progress of 28 cases, all of which have been observed for at least one year following the treatment. Due to the natural vagaries of ulcer symptoms, we called attention in an earlier preliminary report³ to the necessity of conservative conclusions on immediate results. However, in view of the fact that most remissions in ulcer patients will not last for as long as a year, we feel that although our series is small, we can at this time draw fairly accurate deductions as to the value of the treatment, both from the standpoint of immediate and final results.

* Received for publication January 23, 1937.

† Larostidin—Hoffman-LaRoche, Inc.

In order that the conclusions from this study might be judged entirely on the effect of this treatment alone, these patients were requested to carry on their usual activities of life, were given no medicine whatsoever, and advised to eat a general diet. This latter suggestion was somewhat difficult to carry out inasmuch as most of these patients had already taken one or more medical cures and were aware of the efficacy of frequent feedings and alkalies. The patients who obtained relief with the first few injections were quick to branch out on their diet, but the more resistant cases were reluctant to take on foods that they felt had formerly caused trouble.

These cases were in no way selected but routinely placed on the treatment when they presented themselves to the clinic, regardless of the nature of their ulcer. By this method of choice, it is obvious that some cases of perforating and stenosing ulcers which could not normally be expected to respond to medical therapy were included in the series, so, we have shown in the following charts not only the results obtained in the entire series, but also the results obtained in 21 selected cases. The latter group was composed of such cases as showed uncomplicated peptic ulcer and no other physical ailment.

The group is composed of 17 males and 11 females, whose ages varied from 20 to 72 years, the average being 45.2 years (table 1)

TABLE I
Age and Sex

Age	20-29	30-40	41-50	51-60	61-70	71-80
Male	2	5	4	2	3	1
Female	2	3	3	3	—	—
Average age	45.2 yrs		Total cases		28	
Total males	17		Total females		11	

A history of typical ulcer symptoms, with intermittency, food and alkali relief, and epigastric distress two to four hours after meals, was presented in about 90 per cent of the cases (table 2). Four of the patients had had previous hemorrhages. Two cases gave a history of perforation and three cases presented an entirely atypical symptomatology, the diagnosis being

TABLE II
Symptomatology

Epigastric pain or distress	25 cases
Intermittency	26 cases
History of food and alkali relief	24 cases
Hemorrhage	4 cases
Perforation	2 cases
Atypical symptomatology	3 cases
No food or alkali relief	4 cases
Avg. duration of symptoms	8.8 years

established entirely by roentgen-ray findings. The average duration of symptoms was 8.8 years.

Of the 28 cases in the series, 23 were duodenal and five were gastric ulcers (table 3). The roentgen-ray findings were rechecked every three months for one year and at the end of this time two cases of the duodenal

Unimproved	5 cases

ulcer group were considered cured. This deduction was based on the disappearance of all deformity of the cap, as well as a clinical course in which there had been no recurrence of symptoms. Decreasing size of the crater, improvement in the appearance of the bulb, and decreasing activity of the stomach were the criteria on which five cases in the duodenal group were considered improved radiographically. Sixteen of the duodenal cases were unimproved from the roentgenologic viewpoint. None of the five cases of gastric ulcer showed any improvement radiographically. Analyzing these figures, we find that approximately 75 per cent of the cases showed no improvement radiographically, while 86 per cent were considered cured and 21.7 per cent improved.

The clinical results of the entire series show six cases or 21.4 per cent received complete and total relief (table 4), a figure considerably higher than the percentage considered cured radiographically, but a percentage quite in keeping with the radiographic findings if we consider the number of cases

TABLE IV
Clinical Results in Entire Series

Duration of Symptoms	No. of Cases	Complete Relief	Partial or no Relief	Complete Relief with Relapse
1-3 yrs	7	3	2	2
4-5 yrs	3	0	2	1
6-10 yrs	10	3	3	4
11-14 yrs	3	0	2	1
15-20 yrs	3	0	1	2
21 plus	2	0	1	1
Total cases	28			

cured and improved radiographically. This discrepancy is possibly due to the fact that some cases cured clinically may not have been considered cured radiographically because of a remaining scar in the duodenal cap. Eleven cases, or 39.3 per cent, received only partial or no relief, and 11 cases, or 39.3 per cent, received complete relief but relapsed within the first year following treatment. Adding the percentages of the relapsing group to those that received only partial or no relief, we find approximately 80 per cent of the patients received no real permanent benefit from the treatment. However, if we group the relapsing cases that received complete relief with those that received permanent relief, we find that 60 per cent of the patients obtained symptomatic relief, a percentage somewhat lower than our experience with the Sippy management of peptic ulcer.

In the group of 21 selected cases, we find 28.6 per cent of the cases received permanent relief, 23.8 per cent were complete failures, and 47.6 per cent received complete, immediate relief with relapse within the first year (table 5). This group of cases probably more nearly represents the true curve of success and failure, as the stenosing and perforating cases were not included in the final deductions.

TABLE V
Clinical Results in Uncomplicated Cases

Duration of Symptoms	No of Cases	Complete Relief	Partial or no Relief	Complete Relief with Relapse
1-3 yrs	7	3	2	2
4-5 yrs	2	0	1	1
6-10 yrs	7	3	1	3
11-14 yrs	2	0	1	1
15-20 yrs	2	0	0	2
21 plus	1	0	0	1
Total cases	21			

Ten of the patients from the selected group were given a second course of treatment four to six months after finishing the first course, regardless of whether or not they had relapsed within that period. It is interesting to note that of this group, those patients who had previously relapsed have all developed symptoms again following the second course of treatment.

One uncomplicated case has received four courses and has relapsed within 30 to 60 days following each course, although he received complete relief from symptoms during each period of treatment. Sandweiss⁴ has reported that several of his cases became symptom-free with a daily intra-muscular injection of water. We are of the opinion that possibly the above case would be an excellent subject on whom to determine the psychological effect of injection treatment.

Two uncomplicated cases have received three courses of treatment, and all have relapsed from three to seven months after the treatment. The case that relapsed seven months after the treatment shows the longest period of freedom from symptoms that we have found in the relapsing group.

Two of our cases have been operated upon four to six months respectively after the completion of the injections, and in both instances active ulcers were present. One other case died of intra-abdominal complications four months after completing the treatment, and an active duodenal ulcer was found at the necropsy.

In our earlier report, we were of the opinion that the cases in which symptoms had not been present longer than five years were the ones most likely to be benefited, but in the final analysis, we find three cases cured who had had symptoms from six to 10 years, and three cases whose symptoms were less than five years in duration. So it is apparent that the duration of the ulcer has made no difference in the final results except from the standpoint that none of the remaining cases with symptoms for more than 10 years received any improvement.

It has been our experience that most of the patients who received complete relief became symptom-free with the first few treatments, and those cases who received no early benefit did not improve with increasing the number of treatments, as we gave several patients 30 daily injections. One case received 38 daily treatments with no improvement whatever, but became symptom-free on a carefully managed Sippy routine. We have experienced no reactions in any of the 42 cases we have treated and are of the opinion that the treatment is perfectly harmless.

In conclusion, we would like to call attention again to the fact that this treatment will undoubtedly produce remissions in a fairly high percentage of uncomplicated ulcer patients, 76.2 per cent in the selected series, but the permanent relief is no greater than that in various other methods of ulcer treatment and management. We have purposely not used the histidine treatment in conjunction with dietary and alkali routine because we felt that if the treatment were worth while, one of the greatest advantages it offered was the possibility of eliminating the monotonous routine of our usually accepted measures. We also felt that if peptic ulcers were due to histidine deficiency, as proposed on theoretical grounds by the originators, dietary measures would not be necessary. We were able to produce a remission with histidine in only one case of the four in whom dietary and alkali regime had previously failed to give relief. After two years' experience in the treatment of 42 patients with histidine, we are of the opinion that the results obtained do not justify the routine use of this procedure in the management of peptic ulcer patients.

STUDY OF HYPERTENSION IN VETERANS¹

By JOHN A. REISINGER, M.D., *Washington, D. C.*

IN the period from October 1, 1935 to April 1, 1936, the Veterans' Administration Facility in Washington, D. C., discharged 1369 patients who had been under observation and treatment in the wards. Of this number, 82 had hypertension, which is approximately 6 per cent of the total number discharged. Riseman and Weiss¹ quote reports from two European hospitals in which the incidence of hypertension among the male patients examined was 9.6 per cent and 9.7 per cent respectively, and among the female patients 7.9 per cent and 25.9 per cent of the total number of women. In these reports, however, a blood pressure above 140 mm Hg systolic was considered abnormal, while in this series, the figures of 150 mm Hg systolic and 90 mm Hg diastolic have been used as the dividing line. The diagnosis of hypertension depends to some extent upon the examiner, the conditions under which the examination is made, and the reactions of the patients, thus, a single estimation of pressure may be too high, particularly if the patient is under emotional stress. Alvarez² reported hypertension in 53.6 per cent of drafted men, which suggests that the emotional tension of an examination under such conditions increased the blood pressure of a considerable number of healthy men.

The present group under study is composed of veterans of the military services of the United States who were patients in this hospital. Many of them were observation cases and had not previously known of their hypertension.

Only 4.7 per cent of the whole discharged group were females of whom six comprised 7.3 per cent of the hypertensive group.

Among the men, the colored patients represented 8.2 per cent of all discharged and 20.7 per cent of the hypertensive cases. This disproportion is sufficiently great to indicate a greater incidence of hypertension in negro men than in white patients from the service groups.

A characteristic of the population in Veterans' facilities is the limited age period into which the majority of the patients fall. While the range for approximately 1600 patients was from 23 years to 92 years, the average was 45 years with 58.5 per cent between 40 years and 49 years. The average age of all the hypertensives was 49.8 years or approximately five years older than the whole group, with 51 per cent between 40 and 49 years. The colored patients with hypertension averaged 45.5 years of age, while the females with hypertension averaged 52.3 years. The latter group is too small to influence the figures greatly or to be more than suggestive of the trend, but it is significant that the Negroes not only have a relatively higher

* Received for publication January 19, 1937.

From the Cardiovascular Research Unit, Veterans' Administration, Washington, D. C.

incidence of hypertension but the average age at which they appear for treatment is less than that of the white patients (table 1)

TABLE I
Incidence of Hypertension

Over 70	24	1.5	6	7.3

WAR SERVICE AND POST WAR OCCUPATION

Sixty-four patients in this group were in the Service during the World War, one was a veteran of the Civil War, 11 were Spanish-American War veterans, and the remainder were in peace-time service. Among the World War veterans, 32 were overseas, and some engaged in varying amounts of combat service. The records show that six of these received gunshot wounds which in themselves were not severe enough to cause permanent disability, 10 claimed to have been gassed, in most cases with mustard gas, and a total of 26 gave histories of illness or injuries at home or abroad during their service, that may have affected their health subsequently. It is inferred that these men were physically fit upon entering the Service and were more or less disabled following their war-time experiences, although there is no common factor unless it be emotional strain that might account for the development of hypertension.

In many instances, high blood pressure and its complications have not been the reason for seeking medical care. Five patients have been unable to do any work or very little work since discharge from Service. One was discharged because of an injury to his back with subsequent hysterical manifestations, one had a gunshot wound followed by empyema, one had measles with severe complications, one was apparently well on discharge but developed symptoms and signs of serious cardiac disease within two months after discharge, one has been only partially active following pneumonia, and one has worked very little since the Service but did not have a medical record during his enlistment. Another veteran worked intermittently until 1928 but had some degree of heart failure since 1918.

With the exception of the traumatic disabilities, the illnesses most frequently noted were influenza, pneumonia, and rheumatism of various types. The Spanish War veterans usually gave a history of having had malaria, and one man who developed malaria in 1919 stated that he had not been well since. One veteran, who was in the Navy, made over 225 deep-sea dives up to 170 feet and was always sick after coming to the surface as he was

not decompressed. He has an excessively high pressure which has disabled him since the age of 32. It is impossible to say how important these illnesses and traumatisms were in causing hypertension, but in 19 of the 26 cases with wartime medical records, the hypertension was first noted before the age of 40, the average age of diagnosis being about 38 years for these 26, as compared to 41 years for the whole hypertensive group of World War veterans. The earlier recognition of hypertension in those patients who had wartime illness or injury may be due to more or less continuous observation since their discharge.

Official records of 11 patients were available for diagnoses and treatment rendered before the appearance of clinical hypertension was noted.

One patient was first seen in 1931, at which time he gave a history of life-long headaches. He had taken large quantities of a proprietary analgesic. He was an aviator during the War, had influenza and malaria in 1918 and 1919, since which time he had never felt well. In 1931, his blood pressure was 136 systolic and 86 diastolic, his retinal arteries showed moderate sclerosis, the blood chemistry and urine were normal. In 1933, the blood pressure was recorded between 174 and 200 systolic and 106 and 128 diastolic. In 1935, he died of an intracranial hemorrhage following congestive failure.

The headaches and cerebrovascular changes as shown by sclerosis of retinal arteries preceding the hypertension, suggests a relationship between the intracranial circulatory changes and the hypertension.

The second case was seen in 1931 because of gastrointestinal complaints. His blood pressure during that admission was 138 systolic and 80 diastolic, and definite retinal sclerosis with bilateral neuroretinitis was observed without evidence of renal or cardiac damage. In 1933, he was given a diagnosis of hypertension, and in 1935, the blood pressure was 170 systolic and 110 diastolic. He was admitted for treatment of cardiac failure and showed generalized arteriosclerosis, cardiac enlargement, bundle branch block, normal blood chemistry except for a uric acid of 4.8 mg per cent, a trace of albumin and occasional hyaline cast in the urine, and normal P S P (phenolsulphonephthalein elimination). This patient was 39 years of age when first observed. His father had died at the age of 31 of "acute indigestion."

In this case again, the changes in the retinal arteries were the first evidence of vascular disease noted and this suggests that the intracranial vascular lesions preceding the clinical hypertension may have been important causally, although generalized vascular sclerosis appeared comparatively early.

The third patient had been seen in various facilities and offices since 1922. During the War, he had had measles followed by otitis media and arthritis which persisted and greatly crippled the patient. In 1926, he was diagnosed dementia precox and possible endocrinopathy. In 1927, an albuminuria was noted, in 1931, an iritis resulting in loss of vision in one eye and partial loss in the other, and in 1932, hypertension. In 1936, his blood pressure was 170 systolic and 110 diastolic, the blood chemistry was normal except for a blood uric acid of 4.2 mg per cent, and no other evidence of renal disease was found. There was slight cardiac enlargement. The patient still complained of his arthritis, and his mental condition had required institutional care on several occasions.

The severe chronic arthritis and otitis media, the mental illness, and the possible endocrine dysfunction were the important conditions preceding the development of hypertension in this patient.

The fourth patient had been treated in Veterans' Administration facilities since 1923. He had otitis media while in the Service which continued as a chronic sup-

puiative otitis media until 1926 when a mastoidectomy was done. This was followed by a thrombosis of the lateral sinus and an extradural abscess in the middle fossa. He had had headaches since the War and in 1931, a retinitis suggestive of hypertension was noted. At this admission, his blood pressure was 120 systolic and 70 diastolic but his urine showed some albumin, casts, and red blood cells. The blood chemistry and P S P were normal. In 1936, the blood pressure was 144 systolic and 96 diastolic, the blood chemistry and P S P were still normal except that the blood uric acid was 4.9 mg per cent, and the urine showed a trace of albumin and an occasional hyaline cast.

The history of an ear infection persisting for almost 10 years, resulting in an extradural abscess and the evidence of renal involvement with retinal changes may be important.

The fifth patient had been seen in Veterans' Administration facilities since 1919. He had had various diagnoses of hysteria, petit mal, epilepsy and constitutional psychopathic state. During the War, he had rheumatic fever but later saw active service and received a gunshot wound. He was hospitalized on several occasions in mental institutions for psychotic episodes. In 1931, he was observed to have a low grade retinitis with small arteries which showed thickening. The blood pressure at that time was 110 systolic, 90 diastolic, and the urine was negative. In 1934, the blood pressure was 178 systolic, 126 diastolic, the blood chemistry and urine were normal except for a uric acid of 4.9 mg per cent.

This patient was 37 years of age when hypertension was first discovered and changes in the retinal arteries had been noted three years before. He also had mental illness with psychotic episodes.

The sixth patient, a colored veteran, had been seen from 1922 in Veterans' Administration facilities. He had pneumonia during his service and never returned to duty following his illness. Since 1922, he had been diagnosed pulmonary tuberculosis by some and no pulmonary disease by others. Hypertension was first noted in 1929 when the patient was 36 years of age. In 1936, his pressure was 196 to 220 systolic and 130 to 136 diastolic.

The patient had been very nervous, restless and easily frightened, but no definite cause for his disability prior to the hypertension was found except the sequelae of the pneumonic infection.

The seventh patient had been under treatment since 1919. During the War, he was gassed and claimed to have been shell-shocked, following which he was very nervous with many complaints suggesting neurocirculatory asthenia. He was diagnosed chronic bronchitis, tuberculosis by some and not by others, psychoneurosis by some and not by others. In 1934, he was given a diagnosis of hypertension and nephritis. In 1935, his blood pressure was 176 systolic, 116 diastolic, the blood chemistry was normal except for a uric acid of 4.2 mg per cent. The urine showed 4-plus albumin, hyaline and granular casts. The P S P was normal.

The diagnosis of nephritis apparently was based on the presence of hypertension and abnormal urinary sediment, without any history of an acute attack. It was felt, at a later date, that this patient did not have a nephritis primarily but showed renal dysfunction secondarily to hypertension. The trauma during the War and the succeeding psychoneurosis are outstanding in the history preceding the diagnosis of hypertension.

The eighth patient had been seen from 1921 in Veterans' Administration facilities. During the War, he was hospitalized with rheumatism of his legs and erythema nodosum. This condition recurred in 1920 and 1933, as well as an otitis media in 1930. He had had diagnoses at various times of diseased tonsils, effort syndrome, and hypertension in 1931 for the first time. In 1935, his pressure was 156 systolic and 108 diastolic. The blood chemistry was normal except for a uric acid of 4.2 mg

per cent, and the urine was negative. The basal metabolic rate was minus 15 per cent, and he weighed over 200 pounds.

The diagnosis of hypertension was made at the age of 32 years. He had a history of rheumatic infection without cardiac involvement. The comparatively mild hypertension may have been associated with an endocrine dysfunction suggested by the obesity and low basal metabolic rate.

The ninth patient had been seen since 1922 in Veterans' Administration facilities. He was qualified for limited service during the War because of a previous fracture of the left tibia. Since 1918, he had had arthritis requiring bed care for several months of every year. In 1929, a diagnosis of uncomplicated nephritis was made which improved with treatment. In 1934, hypertension was first noted on his record, and in 1936, his blood pressure was 205 systolic, 120 diastolic. There was retinal and peripheral arteriosclerosis. The blood chemistry was normal except for a uric acid of 5.4 mg per cent, and the P S P was normal. The urine showed a trace of albumin in several specimens and an occasional hyaline cast which was not considered sufficient to make a diagnosis of nephritis.

The recurring chronic arthritis with a fairly high uric acid may indicate that the patient had gout since the other renal findings are no greater than might be expected with a blood pressure of over 200 systolic. This patient was a painter by occupation but gave no history of lead poisoning and he had not worked since 1932.

The tenth case had been seen in Veterans' Administration facilities since 1928 and given diagnoses ranging from psychoneurosis with depression to toxic psychosis. When first observed in the hospital in 1930, his blood pressure was reported as 130 to 142 systolic and 90 to 106 diastolic. He stated that since boyhood he had been "high-strung," resented authority, and wanted to be free and independent. He claims to have been slightly gassed and knocked unconscious by an exploding shell during service and at the time of discharge was very nervous. The diagnosis of psychoneurosis, moderately severe, has been continued up to the present.

This patient presents a tense mental reaction without other evidence of organic illness as a possible explanation of his hypertension.

The eleventh patient, a dentist, had been seen as a patient in Veterans' Administration facilities since 1924. In November 1924, he was examined for a Reserve Commission, at which time the blood pressure was reported as 130 systolic and 87 diastolic, heart and arteries normal. Later in the same year, he was given a diagnosis of mitral stenosis which was repeated on several occasions subsequently, as well as the diagnosis of neurasthenia, but in 1936 there was no evidence of heart disease. Hypertension was first noted in 1929. The patient dates his symptoms to the bombing of the hospital in which he was on duty in France, and injury to his head when thrown by the force of the explosion. Since then, he claims that he has been a changed person and has not been able to practice because of his nervous tremor and tension.

There is very little in this patient's history except the long-standing neurasthenia and possible cranial trauma to account for his hypertension. The neuropsychiatric consultant made a diagnosis of cerebral arteriosclerosis apparently on the basis of his mental reactions.

In this group which had been under observation for 5 to 17 years prior to the last admission to the hospital, the medical histories are very dissimilar. Four had had arthritis of various types, three had had otitis media, one with mastoiditis and extradural abscess, one had had pneumonia, one influenza, and one malaria. There were no histories of acute nephritis in this series. The histories of infections during Service are not much different from what might be expected in a civilian population, and the cases are too few to

demonstrate any relation between specific infections and hypertension. Only one patient in this series developed tuberculosis during the War and this one was a female whose hypertension appeared many years after her pulmonary condition was quiescent. Several others were suspected of having tuberculosis but the later course would indicate that this was not the case.

Syphilis has frequently been cited as a causative factor in essential hypertension although this is denied by most authors in recent years. Among the patients who had hypertension, eight had positive blood Wassermann reactions, one a positive Kahn reaction and negative Wassermann and six gave definite histories of syphilitic infection although their blood Wassermann reaction was negative while in the hospital. Fifteen patients, all of whom were males, is an incidence of approximately 18 per cent. A diagnosis of syphilis on the basis of a positive Wassermann reaction only was made on 64 of the whole discharged group or approximately 5 per cent. The incidence of syphilis among the hypertensives is greater even if only Wassermann positive cases are considered, but it is perhaps most important that 11 of the 15 patients or 73 per cent were colored, which is 65 per cent of the total number of colored patients with hypertension. Among the white patients with hypertension, the occurrence of syphilis does not vary significantly from the general incidence. In the Negroes, syphilitic infection if not the basic cause of hypertension, may account for the early development and the severe forms with frequent vascular accidents.

In four of the preceding patients, examination of the retina revealed sclerosis of the vessels several years before hypertension was noted clinically. It has been postulated before that vascular lesions in the brain³ are responsible for many instances of hypertension although Cutler⁴ has offered considerable negative evidence to the contrary. The presence of cerebral arteriosclerosis as indicated by changes in the retinal arteries, before the development of any definite elevation of blood pressure, however, would further suggest the importance of cerebral vascular changes in the causation of essential hypertension.

At least four patients gave histories of cerebral trauma from falls or explosions in their immediate vicinity. One also had done considerable deep-sea diving without decompression which is said to frequently cause intracranial vascular changes. The possibility that cranial trauma may cause brain lesions, resulting in chronic hypertension in some cases, is suggested. It is unlikely that this could be proved by histological studies in view of the limited knowledge of central control of vasomotor centers and the anatomical pathways involved.⁵

NEUROPSYCHIATRIC CONDITIONS

In the group under study who exhibited hypertension, 11 patients were given diagnoses of organic and functional mental disease of various kinds. Five were classified as having dementia praecox, one paresis, one senile

psychosis and four severe psychoneurosis. Several others complained of psychoneurotic symptoms of more or less severity, but the above four developed their illness during the War. The influence of chronic anxiety states and other mental illness on the development of chronic hypertension can only be surmised, but it is true that these conditions are present in many cases before the blood pressure becomes chronically elevated. The effect of emotion in raising the blood pressure acutely is commonly observed and the "high pressure," "quick-tempered," individual not infrequently has hypertension.

As an indication of psychoneurosis, it is interesting that at least eight of the hypertensive patients were addicted to the use of alcohol in large quantities. Thirty-one admitted the moderate use of alcohol and 24 did not use it.

OBESITY

In the series of 82 patients with hypertension, 24 gave a history of obesity in the past or at the time of their admission. These patients had at some time weighed over 200 pounds, which for most individuals is definitely above normal. The age, weight and sex were not considered in this classification but a comparison was made with the incidence of individuals weighing 200 pounds or over, at some time in their life, in a group of 80 patients who had diagnoses of benign tumor, cardiac neurosis and urticaria. None of this latter group suffered from hypertension or wasting illness and only four weighed over 200 pounds. The frequent occurrence of hypertension among obese individuals has often been observed although the mechanism or significance of the relationship cannot be explained.

Endocrine disturbance is often present in both conditions and one of our patients presented a fairly typical picture of a Cushing syndrome with obesity, hypertension and diabetes. Three other patients had diabetes, two of whom were obese while the third was not. The latter patient was 71 years of age and had a comparatively mild diabetes. Hypertension has been reported occurring frequently in diabetes but diabetes is present in only a small percentage of hypertension patients ^{6, 7}

HEREDITY

Information regarding the illnesses of other members of a family is rarely sufficiently complete or accurate to draw definite conclusions concerning the hereditary influence involved in any particular type of illness, the colored patients, especially, often know very little about their parents or their brothers and sisters. Fourteen records did not contain any statement regarding either parent. However, of these patients, 10 were over 60 years of age themselves. The age of the parents at death was shown for 48 fathers and 47 mothers, the average being 65 years and 60 years respectively. The fathers of seven patients were still living and their average age was 73.

years, while 13 mothers were still living with an average age of 69 years. In a few other instances, the ages of the parents were not known, but it is likely they would only have raised the average age as the statements were made that they died of old age or were old and feeble. These figures would indicate that the males survived the females by several years and that the longevity of the parents of these patients with hypertension was well up in the normal range of life expectancy. Practically all of the deaths of parents in earlier life were due to acute infections, accidents and child-bearing, and only four deaths before the age of 60 were from heart disease.

At least 37 of the veterans had one member of their family, composed of their parents and siblings, who had died or were suffering at that time from some form of cardiorenal-vascular disease, the most common being a cerebral accident. Fourteen of these were in brothers and sisters below the age of 60. Eleven families had two members, and four families three or more members beside the veteran patient, with cardiovascular-renal disease.

Compared to a group of 80 non-hypertensive patients, the proportion of parents whose age at death was known in both groups was about the same and the average age at death was several years greater in the parents of the hypertensive patients. The age of a few more of the living parents of non-hypertensive veterans was given than in the other group, but here again, the average age is somewhat greater in the parents of hypertensive patients (table 2).

TABLE II
Parents of Veterans

	No Patients	Fathers				Mothers			
		Dead	Av Age Death	Living	Av Age	Dead	Av Age Death	Living	Av Age
Hypertension	82	48	65	7	73	47	60	13	69
Non-Hypertension Control	80	46	62.8	16	70	41	55.4	16	66

There is a definitely greater incidence of cardiovascular-renal disease in the immediate families of hypertensives than in the non-hypertensive group as indicated by the table (table 3). It is suggestive also that 22 members of the families of the hypertensive patients had had strokes, apoplexy or

TABLE III
Number of Families with Cardiovascular Disease in Other Members than Patient

	Hypertension	Non-Hypertension Control
One other member	37	21
Two other members	11	4
Three or more other members	4	1

paralysis while only three relatives of the non-hypertensive patients had had such conditions as indicated by the records

Twenty-one patients were given a diagnosis of hypertension before the age of 40 and of these, there was at least one other member of the family with cardiovascular-renal disease in nine. This is about the same proportion as in the whole group

The family history of the patients that died showed a high incidence of cardiovascular-renal disease in six, and the other two did not give adequate histories

It is reasonable to suppose that constitutional factors, familial reaction patterns, and habits of living are of some moment in the development of hypertension. This study is suggestive of this influence as indicated by the greater incidence of cardiovascular-renal diseases in the families of patients with hypertension as compared to a non-hypertensive group although the longevity of the parents favored the former. Even those parents who died of cardiovascular-renal disease were on the average above 60 years of age, and not infrequently the statement was made that the parents were over 70 or 80 when they died of a stroke

OCCUPATION

The occupation record was given quite completely in all cases except 10 which included those veterans who had not worked since discharge from service and those who had retired many years previously because of age or disability. Five groups were separated on the basis of the physical work involved in their occupation: 1, clerical work, 2, salesmen and shopkeepers, 3, professional people including doctors, dentists, lawyers, nurses, and army officers, 4, heavy laborers such as farmers, blacksmiths, machinists, laborers, etc., 5, light laborers such as carpenters, painters, housewives, chauffeurs, etc. It obviously is impossible to accurately classify physical effort so dogmatically, but the following distribution with the average age is presented and attention is directed to the low average age of the salesman group and the comparatively higher average age of the clerical and professional groups as compared to the laboring groups. The rather high percentage of the professional class in this series from a general service hospital suggests a high frequency of hypertension in individuals in such occupations (table 4)

TABLE IV
Occupation and Hypertension

	Class	No. Patients	Per cent	Av. Age at Obs.
Clerical	1	10	12.2	52.1
Salesmen, etc	2	12	14.6	44.4
Professional	3	13	15.8	54.7
Heavy laborers	4	18	21.9	49.6
Light laborers	5	19	23.1	46.7
Unclassified	6	10	12.2	56.9

It is impossible to say from the records whether the individuals in the salesman group were high pressure types or not. It seems more likely that they were men with some physical handicap for which they sought treatment earlier and who chose an occupation permitting some irregularity of attendance.

As would be expected from such a hospital population, the laboring groups are the largest. Speculation as to the significance of the younger average age is covered in the next section.

CARDIAC ENLARGEMENT

In many instances, the 82 patients exhibiting hypertension were admitted to the hospital primarily for treatment or study of other conditions. Thirty-four were found to have no objective evidence of heart disease and in six patients with hypertension, the cardiac involvement was considered to be principally of syphilitic etiology.

The average age of the hypertensive patients without heart disease was 49.5 years, only slightly less than the general average for the whole group. Thirty-nine patients were considered to have cardiac enlargement and their average age was 51.5 years. As far as could be determined from the histories given by the patients and the previous records, the patients with cardiac enlargement had been diagnosed hypertensive an average of four years before their present admission, while in the whole group, the presence of hypertension had been known on an average of nine years.

When the incidence of enlargement in the various occupational groups was compared with their proportion of the whole group, it was observed that the heavy laboring group was responsible for the largest percentage with cardiac enlargement, definitely greater than the per cent of this class in the whole group. The salesman and shopkeeper group also showed a higher percentage with cardiac enlargement than would be expected from their representation in the group. Excessive exertion might be expected to contribute to cardiac enlargement but such an explanation is hardly applicable to the salesman group which also showed a low age at the time of observation.

Twenty-six per cent of the patients with enlarged hearts were colored while approximately 21 per cent of the hypertensive group were colored, indicating not only a high incidence of hypertension but also a high per cent with cardiac involvement. The facts that the colored veterans were largely engaged in laboring occupations and that 65 per cent of them had syphilis are undoubtedly important for the explanation of this racial tendency to cardiac involvement.

All the patients with mean pressures above 170 mm Hg had cardiac enlargement. Most of the patients with comparatively low mean pressures also showed cardiac enlargement but their histories and electrocardiograms indicated previous attacks of coronary occlusion or hemiplegia.

Thirty-eight per cent of the patients with enlargement also weighed or had weighed over 200 pounds. Thus 60 per cent of the obese patients were in this group comprising about 18 per cent of all the hypertensive patients. Due allowance for the difficulty in determining heart size accurately in such patients should be made in interpreting this relationship.

In the development of cardiac enlargement in hypertensive patients, the height of the mean pressure, the type of occupation, syphilis, and possibly obesity were probable factors (table 5).

TABLE V
Occupation and Cardiac Enlargement

	Class	Incidence of enlargement Per cent	Incidence in series Per cent
Clerical	1	7.7	12.2
Salesmen, etc	2	17.9	14.6
Professional	3	12.8	15.8
Heavy laborers	4	30.7	21.9
Light laborers	5	15.4	23.1
Unclassified	6	12.8	12.2

ELECTROCARDIOGRAMS

In 48 of the 82 cases, electrocardiograms were reported. Of these, 23 were within normal limits. Six showed only left axis deviation as an abnormality and 19 presented definite abnormalities. The most common finding was inversion of the T-wave in Lead I, which occurred nine times, in three instances associated with inversion of the T-waves in the other two leads, and in one instance, with an inverted T₂ only. Inversion of the T-wave in Leads II and III occurred five times each, but coincided only the three times previously mentioned when all the T-waves were inverted.

The voltage of T-waves was reported low (less than 0.1 millivolt) four times in Lead I, six times in Lead II and three times in Lead III.

The QRS voltage was reported to be less than 0.5 millivolts in all leads in three cases. In the tracing of one of these patients who had had myocardial failure for several years, the QRS complexes were W-shaped and death occurred during his admission. The other two patients had blood pressures that were comparatively low and questionably abnormal. They both had numerous complaints which did not include cardiac pain.

High voltage tracings have been described as more characteristic of hypertension⁸ but none were observed in this series. Low voltage QRS complexes apparently were not related to uncomplicated hypertension.

Three tracings showed deep Q₃ waves which satisfied the usual criteria for significance.⁹ One of the patients gave a history of a severe attack of pain about 10 days before his admission, and his electrocardiogram presented changes suggestive of a healed anterior coronary occlusion and an

acute posterior occlusion. A second patient had a history of precordial pain with cardiac insufficiency for three years preceding his admission and showed also a negative T_3 without left axis deviation or definite cardiac enlargement. It is probable that this patient also had had a coronary occlusion in the posterior portion of the heart. The third patient had had a very high pressure for a number of years, but in this case, the deep Q_3 with an inverted T_3 and left axis deviation may have been the result of a transverse position of the heart in the thorax.

One patient exhibited bundle branch block and one auricular fibrillation. One of the fatal cases showed a coronary occlusion at autopsy and two years previously his electrocardiogram had shown inverted T-waves in Leads I and II. Another patient gave a suggestive history of precordial pain two months before admission and his electrocardiogram showed inversion of T_1 with low voltage of T_2 and T_3 . While only one patient died from an acute coronary thrombosis, the history of several others with their subsequent clinical course, suggested that they had experienced acute attacks probably involving the posterior portion of the heart or small vessels. In any event, characteristic electrocardiographic abnormalities which might not be due to coronary artery disease were not seen in this series.

BLOOD

Polycythemia is sometimes associated with hypertension, and in certain cases the increased viscosity of the blood which results from the increased number of cells may at least be an added factor increasing peripheral resistance. A recent case, not included in this series, exhibited a marked decrease in mean pressure with relief of symptoms when the red blood cells were reduced in number.

When the blood counts of the patients in this series with hypertension were compared with those of a similar sized group of hospital patients without hypertension, the latter group had a greater number with hemoglobin above 16 gm per 100 cc or red blood cells above 5,000,000 per cu mm than the hypertensives. True polycythemia occurred only once in the hypertensive series and the incidence of this condition as a causative factor in hypertension cannot be great. It might be expected that a secondary polycythemia would develop, particularly in those patients with much arteriosclerosis involving pulmonary vessels, but this was not the case, perhaps because of the age group involved.

Anemia may be observed in patients with hypertension, particularly those associated with or due to renal disease. In this series, 31.2 per cent of the patients had a hemoglobin content of less than 14 gm per 100 cc in their blood, while in the control group, the percentage of patients with a hemoglobin below 14 gm per 100 cc was 21.3 per cent. Only eight of the 25 hypertensives with some degree of anemia had manifestations of kidney dysfunction, principally albuminuria and cylindruria (hyaline casts), micro-

scopic hematuria having been reported only once and an elevated N P N (non-protein nitrogen) three times

RENAL FUNCTION

The association of renal disease with hypertension is commonly observed but the etiological relationship of one to the other is usually obscure. Unless there is a history of an acute nephritis or some other renal condition such as polycystic kidney, the signs and symptoms of renal involvement seem to follow the development of hypertension.

The recent investigations of Goldblatt et al¹⁰ and of Wood and Cash¹¹ demonstrate that hypertension of varying degrees of severity may be produced in dogs by constriction of the renal arteries without causing apparent loss of renal function. It is possible that a mild involvement of the kidneys occurs in man which may not affect the function or cannot be detected by our clinical methods, but is sufficient to cause an elevation of blood pressure. At present, such a hypothesis would probably involve a chemical factor causing generalized constriction of the arterioles, and confirmation of such an etiological theory in human beings has been and will continue to be confronted by many technical difficulties and opposing data.

In this series, only two patients gave a history of an acute renal involvement preceding or accompanying the hypertension, one an acute nephritis, and the other a pyelonephritis with obstructing renal calculi.

Various tests of renal function were performed on 56 of the 82 patients and while some show changes which were interpreted as indicating renal dysfunction, not infrequently the kidney failure has been secondary to congestive heart failure. In these cases, if the patient regained his cardiac compensation, the renal function became normal.

In a control group of 63 hospital patients not exhibiting increased blood pressure, the N P N was reported to be greater than 35 mg per cent in 11 or 17.4 per cent, and of these, two had definite arteriosclerosis, one died of a coronary occlusion, one had chronic nephritis and the remainder had other severe systemic illnesses. Determinations of the N P N were reported for 56 of the hypertensive patients, and of these, 14 or 25 per cent were above 35 mg per cent. The highest value was 88.3 mg per cent for a patient who gave a definite history of renal obstruction. It appears that an elevated N P N occurs comparatively infrequently in hospital patients who do not have hypertension or other evidence of cardiovascular involvement.

The blood uric acid was reported on the same patients in the two groups, 44 per cent of the hypertensives had a blood uric acid of 4 mg per cent or above, as compared to 27 per cent in the control series. As indicated in the table (table 6), this is due largely to the number of hypertensive patients with a slight increase in the concentration of uric acid (from 4 to 5 mg per cent) and the disproportion would be even greater if the patients with heart disease as well as the hypertensives were excluded from the control group.

TABLE VI
Blood Uric Acid in Patients with and without Hypertension

Uric Acid mg per cent	Hypertensives per cent	Control per cent
4-5	32.1	17.4
5-6	5.1	7.9
6-7	1.8	1.6
7-8	5.3	0

About half of the hypertensive patients with elevated uric acid did not show any other evidence of renal disease as indicated by the non-protein nitrogen, phenolsulphonephthalein elimination, specific gravity, microscopic examination, and albumin. The four patients with a uric acid above 6 mg per cent also had N P N's above 35 mg per cent, but only five of the 21 with uric acids between 4 and 6 mg per cent had elevated N P N's. Five of the nine cases in which both the uric acid and N P N were elevated died, but in only one of these was death preceded by uremic symptoms and the others represented advanced cardiac failure.

Nine of the 14 patients with N P N above 35 mg per cent had uric acids above 4 mg per cent, five being above 5 mg per cent. This suggests that an elevation of the blood uric acid occurs more frequently in hypertensive renal insufficiency than an elevation of the N P N and the two values do not necessarily vary together. In the control series, only three patients out of 46 with a blood uric acid of less than 4 mg per cent had N P N's above 35 mg per cent, while seven out of 17 patients with blood uric acid above 4 mg per cent had N P N's above 35 mg per cent. The magnitude of increase in either value was not necessarily reflected in the other, thus the highest N P N which was 63 mg per cent was accompanied by a uric acid between 4 and 5 mg per cent, and the highest uric acid concentration, between 6 and 7 mg per cent, was obtained in a patient with an N P N of only 38.9 mg per cent. The uric acid concentration frequently is increased without other evidence of renal dysfunction and in conditions which are not commonly associated with renal damage. When the concentration was elevated in patients with hypertension, it probably indicated decreased kidney function and when higher concentrations occurred, the prognosis was unfavorable. Five of seven hypertensives with uric acid above 5 mg per cent died and the other two had evidence of recent coronary occlusions which they survived. The N P N in both of these latter cases was normal and it is suggested that the hyperuricemia was extra-renal in origin. Dependence on the estimation of the retention of one chemical substance in the blood is obviously very unsatisfactory for detecting a reduction in renal function in hypertension.

The elimination of phenolsulphonephthalein injected intramuscularly in two hours was estimated in most of the control series along with uric acid

and N P N In only one case out of 16 in which the uric acid was above 4 mg per cent, was the P S P below 40 per cent This method of performing the examination apparently gives very little information in lesser degrees of renal failure

The highest specific gravity reported for any specimen of urine during the patient's stay in the hospital was recorded In 11 cases the specific gravity was less than 1 020 but in five of these, no albumin or abnormal findings in the urine sediment were reported Six showed varying amounts of albumin, three showed hyaline and granular casts and two showed some nitrogen retention in their blood

In the control group, the urine of only nine out of 76 patients showed a specific gravity below 1 020 Five of these had hypertension or arteriosclerosis, three had albuminuria and two moderate nitrogen retention The opinion has frequently been expressed by other investigators that concentration tests are of particular value in evaluating kidney function, but good cooperation on the part of the patient is essential In our experience, this is not always obtained on general wards that can not be closely supervised

Twenty-one in the hypertensive group showed varying amounts of albumin in their urine with a specific gravity of more than 1 020 No attempt was made to correct for the albumin

Routine determinations of urea or creatinine clearances were not made in this series It is generally conceded that such studies are of more value than single estimations of one of the nitrogenous blood constituents but even the clearances are subject to wide variations and require considerable supervision The routine performance of various laboratory examinations by technicians without proper evaluation by the clinician of the conditions under which the examination was made or the proper control of the patient may give data that are more confusing than helpful A limited number of well conceived, properly performed procedures are of more value in the general study of a patient with hypertensive heart disease than many random examinations less carefully controlled

DEATHS

In this small series of hypertensives, there were only eight deaths, or a mortality of 9 7 per cent, with an average age at death of 53 years as compared to the whole discharge group in which there were 91 deaths or a mortality of 5 6 per cent and an average age at death of 52 years In this latter group, the average age at death of the colored patients was 46 years and of the white patients 53 8 years

One of the patients, aged 42 years, had had headaches all his life as had his mother During the War, he was an aviator but did not go overseas He had malaria from 1919 to 1922 and had not felt well since In 1931 when first examined, his blood pressure was 138 systolic, 86 diastolic, his retinal and peripheral vessels showed some thickening but there was no evidence of renal or heart involvement

In 1933 his blood pressure was 200 systolic, 128 diastolic. His headaches were more frequent and associated with nocturia.

In 1935 he was admitted to the hospital with congestive heart failure which improved. His blood pressure was 215 systolic and 140 diastolic. The N P N was 43.7 mg per cent on admission but dropped to 33.3 mg per cent as the signs of heart failure disappeared. About one month after admission, he was feeling very well when he suddenly complained of a sensation of acid being poured over his face and left side. He soon developed unconsciousness and died.

The postmortem examination revealed a small hemorrhage in the pons, and unusually marked sclerosis of the vessels of the Circle of Willis. The heart showed hypertrophy of the left ventricle with a small area of healed infarction. The kidneys were about normal in size, the larger vessels showed sclerosis, the glomeruli were large and some showed hyalinization.

The second patient, aged 64, was admitted in an unconscious state and died within 72 hours. A history was not obtained but he presented evidence of a right-sided hemiplegia with a hypertension of 178 systolic and 120 diastolic. The blood N P N was 70.5 mg per cent, uric acid 7.9 mg per cent and the urine showed a few red blood cells, many hyaline and granular casts and 1-plus albumin.

The postmortem examination failed to reveal a localized cerebral lesion of any kind but the brain and ventricles were filled with fluid resembling the so-called alcoholic wet brain. The cerebral vessels were definitely sclerotic. The kidneys were somewhat small with adherent capsules and decreased cortical width. Certain areas showed fibrosis with complete obliteration of the glomeruli while others were distended. The heart was enlarged and showed swelling of the muscle fibers with considerable interfibrillar connective tissue. Death apparently was due to renal failure.

The third patient was 45 years old and colored. He had worked as a laborer until a few weeks before his first admission in 1933 at which time he had congestive heart failure. The highest blood pressure obtained during his hospitalization was 148 systolic and 105 diastolic. His renal function was good. He was admitted in extremis about two years later and at autopsy the heart was enlarged and presented a saucer-like fibrous dilatation near the apex and a fresh mural thrombus beneath an area on the left ventricular wall in which the musculature was necrosed and infiltrated with polymorphonuclear cells. The kidneys were small and contracted showing cellular infiltration and intertubular fibrosis. The larger vessels were definitely sclerotic and an occasional glomerulus was obliterated.

The fourth patient was a Spanish-American War veteran, 66 years old. He had had a diagnosis of high blood pressure and heart disease for many years but had been able to work as a steam engineer until three months before his admission. He gave a history of a recent intestinal hemorrhage which had resulted in a profound anemia and apparently heart failure.

The postmortem revealed no tumor of the gastrointestinal tract but an area near the splenic flexure with many bleeding points from distended veins. The aorta above the sinuses of Valsalva down to the iliac bifurcation was the site of a severe arteritis with loss of elastica, irregular fibrosis, ulceration, hemorrhage into the wall with fatty change, and calcareous plaque formation. The heart showed fragmentation, swellings and granularity of the muscle fibers. The kidneys showed dilated tubules filled with detritus with focal reaction and fibrosis about some glomeruli, although the tubular involvement was the most striking. The liver showed a perlobular round cell reaction and evidence of cell degeneration which was called an infectious hepatitis. There was a small adenoma in one adrenal. It was felt that death was due to an infectious aortitis with the intestinal hemorrhage as contributory.

The fifth patient was a World War veteran, aged 45. His only illness during service was trench mouth and he had been well since discharge until 1929, when he

had had kidney stones for which he was cystoscoped. It is not known what his blood pressure was then or the exact location of the stones, but from that time he had not been well. In 1935 he was treated in another hospital for nephritis and subsequently in this hospital where he died. Because of the high blood pressure, evidences of renal insufficiency and cerebral symptoms, a diagnosis of uremia was made. Postmortem examination was refused but this case was considered to be a chronic nephritis with secondary hypertension and uremia.

The sixth patient was 74 years old and had served as a Medical Officer during the World War. He was admitted because of senile psychosis and congestive heart failure, apparently dying of bronchopneumonia. Postmortem examination revealed the usual changes of arteriosclerotic heart disease in the heart, blood vessels and kidneys.

The seventh patient was a World War veteran, aged 45. He had known of his hypertension for at least five years and recently had complained of marked cardiac insufficiency. He was semi-stuporous when admitted, had an extremely high blood pressure with papilledema and numerous areas of retinal exudate. Kidney function as evidenced by the blood chemistry and urinary findings was normal. This was considered a malignant hypertension with cerebral edema. Postmortem examination was not permitted.

The eighth patient was a World War veteran, aged 41. He had had scarlet fever, diphtheria and empyema in early childhood, typhoid fever at age 15, and during the War received a gunshot wound and a burn with liquid fire. He was also confined in a German prison camp for four months during which time he first noticed dyspnea and edema. Since discharge from the Army, he had been able to do some work as a salesman until about 1928, but always had some cardiac insufficiency. On admission to the hospital in 1934, he was in severe congestive heart failure and made very little improvement during his 18 months hospitalization. Although he presented evidence of renal insufficiency, this was considered a result of his myocardial failure. An autopsy was not performed. The diagnosis was hypertensive heart disease with congestive failure.

Three of the patients, therefore, were over 60 years of age, one died of bronchopneumonia with congestive heart failure, one apparently died of uremia while the third died following severe intestinal hemorrhages and had a marked aortitis, probably infectious in origin. The remaining five patients were between 37 and 47 years of age at the time of their death and a common factor that may have been responsible for their severe and comparatively short course is not apparent. The immediate family histories indicated a fairly high familial tendency to cardiovascular disease. Renal injury appears to have been an early factor in one case while marked cerebral vascular changes may have been important in two other cases. Only one patient died of an intracranial vascular accident. The two patients that died of congestive heart failure presented evidence of myocardial damage from coronary artery disease.

SUMMARY AND CONCLUSIONS

The incidence of hypertension in 1369 veterans was 6 per cent.

There was a comparatively greater incidence of hypertension among the negro patients whose average age was about five years younger than that of white patients.

A high proportion of the negro patients have syphilis which may account for the early and more serious involvement

The morbidity history during service and subsequently, did not implicate any particular infection as a precursor of hypertension

Involvement of the retinal arteries with a sclerotic process was observed four times before the blood pressure became chronically elevated. This suggests involvement of the cerebral circulation as a factor in the causation of some cases of hypertension

Psychotic and severe psychoneurotic manifestations were found in 13 per cent of the cases. Four patients had suffered cerebral trauma. It is suggested that certain chronic emotional reactions and brain injuries may influence the central regulation of blood pressure

About one-third of the patients with hypertension had been obese at some time in their lives as evidenced by body weight over 200 pounds

A definitely greater incidence of cardiovascular-renal disease was reported in the immediate families of hypertensive subjects than in a control group

The more laborious physical occupations were the most common means of livelihood for about 45 per cent of the group, and the average age of the patients was lower than the professional and clerical groups

Cardiac enlargement was apparent in about one-third of the patients. The height of the mean pressure, occupation, syphilis, and possibly obesity, were the most prominent factors associated with enlargement

Typical electrocardiographic changes that are not characteristic of coronary artery disease were not noted

Polycythemia was present in only one hypertensive patient while one-third showed some degree of anemia

Examination of renal function in 56 patients revealed abnormalities of one or more findings in approximately 60 per cent of the cases. A slight rise in the blood uric acid occurred most frequently

There was very little correlation between the uric acid and the non-protein nitrogen values

Congestive heart failure was frequently responsible for renal failure

Death occurred in eight cases or approximately 10 per cent

CASE REPORTS

TULAREMIC MENINGITIS

Report of Case with Postmortem Observations *

By EDGAR R. PUND, M.D., F.A.C.P., and MILFORD B. HATCHER, M.D.,
Augusta, Georgia

THE histopathology of tularemia is adequately described in the literature notwithstanding the few reports of postmortem examinations. But because there are few reported necropsies the pathology of the disease is of particular interest in regard to the distribution of the lesions. Last year Bernstein was able to collect only 18 necropsies and to these he added three of his own. We have reviewed these cases and three additional reports by Beck and Merkel, Amoss and Sprunt, and Kavanaugh to determine the distribution of the lesions. This study was prompted by the occurrence of a fatal case of tularemia which was diagnosed at autopsy, and in which the outstanding feature was meningitis. Because there is only one report that describes the pathology of tularemic meningitis and furthermore because in our case lesions were observed in organs where they have not been previously observed, this case is of unusual interest.

CASE REPORT

A negro girl, aged 12, was admitted to the hospital on the third day of her illness. The history was obtained from the father who had been separated from his daughter and it is therefore brief and incomplete. No reason for the lesion on the forearm could be obtained.

The present illness began with fever, abdominal pain and headache, followed by nausea and vomiting 24 hours later. The patient appeared very ill, was semiconscious and the skin was hot and dry. Temperature was 105.8° F, pulse 106, and respirations 24. Blood pressure was 140 systolic, 100 diastolic. The lips were parched and the tongue furred in the center and glazed at the margins. Pharynx and tonsils appeared congested. Impaired resonance was elicited over the right pulmonary apex and scattered râles were heard at the right base. The abdomen was distended, tympanitic and diffusely tender, especially over the cecum and spleen. On the flexor surface of the left forearm near the wrist was an ulcer 3 cm. in diameter, which was surrounded by several small vesicles. The reflexes were normal. The clinical impression was typhoid fever.

Pyrexia was continuous during the eight days of observation, between 103 and 106.2° F, pulse increased from 106 to 160 and respirations from 26 to 40. Culture of the throat proved negative for diphtheria, two stool cultures failed to reveal the *Bacillus typhosus* and the Widal reaction was negative. Total leukocyte count was 8,700, with polymorphonuclear leukocytes 65 per cent, small lymphocytes 33 per cent and large lymphocytes 2 per cent. The red blood cell count was 4,100,000 and the

hemoglobin estimated at 85 per cent. The tuberculin skin test was negative. On the fifth day of hospitalization the neck was stiff and Brudzinski's and Kernig's signs became positive. The following day semiconsciousness was followed by coma. The abdomen became rigid. Tuberculous meningitis was now thought to be a possibility, although the diagnosis of typhoid was not relinquished and an intestinal perforation was considered. The cerebro-spinal fluid revealed 114 cells per cu mm, was under 18 mm Hg pressure but yielded negative tests for globulin. The Wassermann reaction on the spinal fluid was negative. The next day the cell count was 200 and the pressure 22 mm Hg. Prolonged search in films from both specimens failed to reveal tubercle bacilli. Blood and spinal fluid cultures remained sterile and the blood serum failed to agglutinate the organisms of undulant fever. Coma continued and death occurred the eighth day of hospitalization or the tenth day of her illness.

Necropsy

A necropsy was performed nine hours after death.

The body was that of a wasted negro female child. An ulcer 3 cm in diameter with a necrotic base was observed on the palmar surface of the left forearm just above the wrist. In the pia-arachnoid innumerable minute yellow foci were regularly distributed but barely visible over all surfaces of the brain. The cerebro-spinal fluid was yellowish. The cord was not examined.

The peritoneal cavity contained about 400 c c of clear light yellow fluid. A small amount of fibrinous exudate was seen on the serosa of the appendix, otherwise the peritoneal surfaces were smooth and glistening. The right pleural cavity contained some 25 c c of turbid fluid and the surfaces were dull and congested. The left pleural cavity contained a like amount of clear fluid and the surfaces were smooth and glistening. In the middle anterior part of the upper lobe of the right lung a firm airless area about 5 cm in diameter was palpated. This, on section, was wedge-shaped, granular and pink but the central part 1 cm in diameter was yellow and caseous. Otherwise both lungs were alike. They were heavy and soggy but crepitant. Cut surfaces were wet, yielded much frothy fluid and were mottled with slightly raised reddish areas, more numerous in the right lung. The mucosa of the trachea and bronchi was congested. The tracheo-bronchial lymph nodes were enlarged to 2 cm in diameter and an occasional small yellow focus was seen against the moist gray background.

Through the capsule of the liver, especially near the inferior border, numerous minute yellow areas were visible and a few similar foci were seen on the cut surface. The spleen was a little enlarged, weighing 130 grams. Its capsule was studded with numerous yellow spots. Similarly the cut surface was studded with round yellow foci, the largest about 0.3 cm in diameter. The mucosa of the appendix in its distal third was necrobiotic and ulcerated. The lymph nodes of a group near the cystic duct were slightly enlarged and several contained small caseous foci. Some three or four left axillary lymph nodes had attained a size of 2 cm in diameter each and were filled with caseous areas, the largest 1 cm in diameter. No noteworthy changes were noted in the other viscera.

Microscopic Examination

The floor of the ulcer of the forearm showed necrosis which involved the subjacent subcutaneous tissue. In the necrotic material shadows of macrophages were seen. The tissues immediately around the area of necrosis were infiltrated with de-

generating polymorphonuclear leukocytes and lymphocytes. Ten representative sections from the brain were studied. In the extreme cortex of the cerebrum and in the submeningeal part of the pons there were numerous minute, rather wedge-shaped collections of small round mononuclear cells and an occasional polymorphonuclear leukocyte. Centrally in the foci was much nuclear and cytoplasmic detritus. The small mononuclear cells displayed pyknotic nuclei. The cytoplasm while generally scant was occasionally increased and foamy, thus suggesting microglial origin. The brain tissue around the foci was slightly rarefied. Many of these aggregates were

FIG 1 Section from meningeal surface of pons. Note the wedge-shaped area infiltrated with small mononuclear cells. This focus is confined within the substance of the brain, however, there is a diffuse meningitis. $\times 240$

confined within the substance of the brain, but the larger ones extended into the leptomeninges (Figures 1 and 2). The leptomeninges were furthermore diffusely infiltrated with small round cells and polymorphonuclear leukocytes. A tendency to focal coagulation was noted in the infiltrate. The exudate in the meninges extended a short distance along the vessels into the submeningeal tissue. Beneath the ependyma of the lateral and fourth ventricles smaller foci similar to those of the cortex and pons were found. The ependyma remained intact. Endothelial swelling and proliferation were noted in some of the vessels nearby. No lesions were observed deep in the

brain The diffuse infiltration of the meninges was noted between the folia of the cerebellum and here and there were deposits of coagulated serum Slight rarefaction of the submeningeal part of the cerebellum occurred, but no inflammatory foci were seen In the choroid plexus there was nothing noteworthy

In the thymus reticular-cell hyperplasia and occasional giant cell formation were noted The airless area in the right lung was caused by a pneumonic infiltration The alveoli were filled with fibrin which enmeshed a few large mononuclear cells, lymphocytes and nuclear detritus Caseous necrosis of the lung and exudate occurred centrally Similar scattered smaller areas and many necrobiotic areas of local hemoi-

FIG 2 Section from meningeal surface of cerebral cortex The lesion is similar to figure 1, but extends into the meninges $\times 240$

rhage and edema were seen in other sections from the lungs In the liver the Kupffer cells appeared prominent Numerous round caseous foci without cellular detail were encountered Necrotic areas of varying size were distributed in the splenic pulp but were more often observed in the lymph nodules Macrophages with indistinct outlines could be seen in the periphery of some of these foci An occasional necrotic focus extended into and some through the capsule A thin sheet of exudate of fibrin, nuclear detritus and an occasional recognizable macrophage covered the spleen Also there was diffuse hyperplasia of the reticulo-endothelium and the sinuses were congested

Coagulation necrosis of minute aggregates of large mononuclear cells was noted

in the medulla and reticular zone of the suprarenal. The endometrium of the uterus was diffusely infiltrated with macrophages, some of which were collected in small groups which appeared necrobiotic (figure 3). Many macrophages were filled with engulfed particles of nuclear debris. In the distal end of the appendix the mucosa and the submucosa were infiltrated with many large mononuclear cells laden with nuclear debris. There was confluent focal necrosis of the mucosa with ulceration. An exudate of fibrin and macrophages was present on the serosa (figure 4). In the axillary, tracheo-bronchial and supra-pancreatic lymph nodes there was diffuse

FIG 3 Section from endometrium. Disorganization of the endometrium and infiltration with numerous macrophages, some engulfing nuclear detritus. There is a tendency to grouping of these cells. $\times 1000$

reticulo-endothelial hyperplasia and the sinuses were crowded with macrophages. Necrotic foci without cellular detail were noted. The largest areas occurred in the axillary nodes.

No acid fast organisms could be found in sections from the brain, lymph nodes, lungs and spleen. Routine sections from the heart, aorta, thyroid, kidney, bladder, ovary and pancreas revealed no noteworthy changes. Blood serum, obtained at necropsy and examined by the laboratory of the Georgia State Board of Health, agglutinated *Bacterium tularensis* in dilutions from 1:640 to 1:1280.

FIG 4 Section from proximal third of appendix. Note the necrosis and ulceration of the mucosa. Dense infiltration with macrophages. $\times 75$

COMMENT

In this case the lesions of the central nervous system are of especial interest both from the clinical and pathologic standpoint. Meningeal symptoms have been noted not uncommonly in patients with tularemia, but the existence of tularemic meningitis was first demonstrated by Haizlip and O'Neil. In their fatal case with meningeal symptoms the brain and cord were not examined at necropsy, but injection of the spinal fluid produced tularemia in a guinea pig. In the literature we found only one description of the histopathology of tularemic meningitis, the case reported by Bryant and Hirsch. They described lesions in the meninges, submeningeal brain tissue, ependyma, subependymal tissues and choroid plexus. The involvement of the brain was considered an extension from the lesions of the meninges. Our observations differ from theirs in that isolated foci were seen within the confines of the brain (figure 1). The difference is probably due to the fact that our case represents an earlier stage in the pathology of the disease, their patient died on the sixteenth day of illness while ours died on the tenth day. It would seem from our observation that the meningitis occurred secondary to tularemic encephalitis. Lesions in the brain

without meningitis have been reported by Hartman. In a case of tularemia he found soft, grayish yellow, necrotic or hemorrhagic areas from 0.5 to 3 mm in diameter in the corpus callosum, basal nuclei, pons and the adjacent tissue. Microscopically these lesions were characteristic of those produced by the *Bacterium tularensis*. The manner of production of tularemic meningitis is probably the same as in tuberculous meningitis. Rich and McCordock have shown that tuberculous meningitis has its origin in the discharge of bacilli into the cerebro-spinal fluid from adjacent older caseous tuberculous foci. In the 24 necropsies previously reported, the brain and meninges were examined in only four cases. Two of these exhibited the lesions described above. The case of Foulger, Glazer and Foshay showed no noteworthy changes in the brain and meninges, while Palmer and Hansmann described a minute pontile hemorrhage and noted elevations on the pia-arachnoid due to several layers of fatty endothelial cells.

Our report is of further interest because lesions were observed in the appendix, thymus and uterus. In the reported 24 necropsies the inflammatory reaction of tularemia was observed in the spleen in 21, lungs in 20, lymph nodes in 20, liver in 19. Involvement of the other organs is rare. Our case exhibited microscopic foci of necrosis in the suprapneural. Francis and Callender have previously noted lesions here. Baidon and Berdez described congestion and swelling of Peyer's patches and solitary follicles of the intestine, and numerous small yellow patches were noted in the mucosa of the stomach and of the small and large intestine, but they did not describe these lesions microscopically. Simpson, and Bunker and Smith observed congestion of the mucosa of the stomach and intestines. Foulger, Glazer and Foshay described the lining of the entire gastrointestinal tract as dull, dirty, grayish pink with engorgement of the blood vessels. Microscopically they observed a diffuse and focal lesion on the serosal surface which was characteristic of tularemia. In Bernstein's first case scattered punctate hemorrhages were seen in the gastric mucosa, in the second, ulceration of the esophagus was noted, in the third, a necrotic focus occurred in the tonsil. Beck and Merkel described grossly and microscopically small ulcers of the stomach, duodenum, ileum and ascending colon which showed the typical necrosis and leukocytic infiltration. The cellular infiltration was confined to the mucosa. There was a fatal case of the typhoid form caused by the ingestion of rabbit. In our case there was a distinctive tularemic appendicitis with local peritonitis which was recognized grossly and confirmed microscopically. No other lesions were seen in the gastrointestinal tract. Sections from the proximal two-thirds of the appendix revealed no lesions. Here then, we have a focal involvement of the appendix which could be hematogenic, yet the possibility of a primary intestinal lesion should be considered. As mentioned above, the only case that exhibited ulcers of the stomach and intestine was reported by Beck and Merkel and in this instance the infection was caused by ingestion of rabbit. It is not unreasonable to think that there may be two sites of inoculation, especially since the person who dresses the infected animal usually eats it. This would explain the fulminant course of some cases because of easy hematogenous dissemination from the intestinal tract. That it is not necessary for the ingested organisms to produce a gastrointestinal lesion is evidenced by the report of Amoss and Sprunt. In their case no gastrointestinal lesions were found although the disease was contracted by ingestion of rabbit. The ap-

pendicitis and serositis of the spleen explain the abdominal tenderness in these regions and the rigidity that developed later

Involvement of the thymus and uterus has hitherto not been reported. While we observed no foci of necrosis in the thymus, there was hyperplasia of the reticulum, a change also noted in the liver, spleen and lymph nodes. The thymus was the only site where giant cell formation occurred. In the uterus of our case there was diffuse endometritis. Kavanaugh observed three patients who contracted tularemia during pregnancy and were delivered of normal babies during the height of infection. In one case labor was premature. Nor did coexisting tularemia endanger pregnancy in the patient of Bowe and Wakeman. A lesion of the uterus probably occurs rarely yet is one to be considered when pregnancy is complicated with tularemia.

SUMMARY

A case of tularemic meningitis is described.

The meningitis is apparently secondary to hematogenic encephalitis.

The distribution of the lesions of the reported fatal cases of tularemia is summarized and involvement of the uterus, thymus and appendix is described.

The possibility of double infection, by way of the skin and gastrointestinal tract, is suggested.

RENAL AMYLOIDOSIS WITH CLINICAL FINDINGS SUGGESTIVE OF POLYCYSTIC KIDNEY *

By FRANK L JENNINGS, M D, F A C P, *Oak Terrace, Minnesota*, HUGO O
ALTNOW M D, F A C P, and GEORGE K HIGGINS, M D,
Minneapolis, Minnesota

SINCE the beginning of the aseptic era in surgery, general amyloidosis appears to be common only in sanatoria for the care of tuberculous patients. Dixon reported 100 cases of pulmonary tuberculosis, 70 of whom had amyloidosis. Perla and Gross reported 100 cases of amyloidosis out of 112 cases of pulmonary tuberculosis, and Saleeby 41 out of 50 cases. In a series of 579 autopsies at Glen Lake Sanatorium, 109 cases of amyloidosis were discovered, an incidence of 19 per cent. The incidence is less than is usually quoted by the various authors from other sanatoria. Rosenblatt found amyloidosis in 24.4 per cent of 451 necropsies and Perla and Gross in about 25 per cent of 400 post mortems.

Of our 109 cases of amyloidosis, the following was in every respect the most unusual.

CASE REPORT

At the age of 16 years, the patient had a cervical adenitis, at 18, cough, expectoration containing tubercle bacilli, high fever, and a pulmonary hemorrhage. Upon his admission to the Sanatorium in September 1921, shortly after the above symptoms were noted, fibroid pulmonary tuberculosis of the right middle and the left upper lobe was present as well as cavitation in the left upper lobe with a small spontaneous pneumothorax at the apex. The urine showed no abnormalities, and his blood pressure was 116 systolic and 60 diastolic. In 1922, a diagnosis of intestinal tuberculosis was made. Sufficient retrogression of both his pulmonary and intestinal lesions occurred so that on November 1, 1924, he was discharged with his tubercu-

* Received for publication November 4 1936

losis considered arrested. He remained in good health for three years and had, during this interval, many urinalyses which showed no abnormal findings.

In 1927, albumin was found in the urine in addition to hyaline, granular, and waxy casts. In February 1928 he developed an upper respiratory infection associated with pain in the right lumbar region. His blood pressure was 153 systolic and 105 diastolic. His urine contained 3 plus albumin and many casts, phenolsulphone-phthalein excretion was 22.5 per cent, blood urea 38 mg, and non-protein nitrogen 77 mg per cent. In January 1930, he was confined to bed for four days because of an acute upper respiratory infection, his right kidney was palpable and tender at this time. He had many recurrences of these respiratory infections and "kidney pains." In February 1932, the lymph nodes on the right side of his neck became palpable, enlarged, and eventually suppurated with the formation of a sinus which healed after four months.

Between 1930 and 1932 his blood pressure varied between 130 systolic and 88 diastolic and 148 systolic and 102 diastolic. In May 1932, it was 128 systolic and 80 diastolic. His urinalysis showed specific gravity 1.017, albumin 3 plus, a few hyaline casts with fat droplets and very occasional granular casts. The hemoglobin was 87 per cent (11.98 gm) and red blood cells 4,600,000.

Following an acute upper respiratory infection in February 1934, the blood pressure was 144, and the urine analysis showed the following: specific gravity 1.017, albumin 4 plus, a few hyaline and granular casts. Although the patient was known to have had a persistent and usually heavy albuminuria for about six years, and on several occasions a slight transient edema, he had no enlargement of his liver or spleen nor demonstrable active tuberculosis at this time. Because of the urinary findings, a diagnosis of amyloidosis was made.

An acute upper respiratory infection in October 1934 was followed by repeated vomiting for several days, so that fluids could not be retained. Urine showed albumin 4 plus, erythrocytes, many leukocytes, and many casts, blood non-protein nitrogen 39 mg and urea nitrogen 27.3 mg per cent. Blood pressure 126 systolic and 90 diastolic. No edema was present. This episode marked the onset of the terminal phase of his illness. Upon advice, he resigned his position which he had held since 1925.

He was hospitalized on October 25, 1934. His blood pressure was 126 systolic and 90 diastolic. Urinalysis showed specific gravity 1.012, albumin trace, white blood cells 10-15, red cells 1-2 per high power field. Non-protein nitrogen was 39 mg, blood urea nitrogen 27 mg per cent. There was a gradual drop in urinary output, and on November 1 and 2, his output was only 100 cc and 80 cc respectively. On the day of the low output his blood urea nitrogen was only 18.5 mg and creatinine 1.9 mg per cent. For the previous three days his intake was never below 2000 cc and on November 1 reached a maximum of 2950 cc. On November 2, the patient was drowsy, and his speech was retarded. On November 3, he was given two intravenous injections of 25 per cent dextrose in normal saline, 300 cc each, and on that day his output increased to 325 cc. The Karell treatment was instituted on the same day with 210 cc of skimmed milk every six hours. November 4, the 24 hour output reached 580 cc. On November 6, the Karell treatment was discontinued, and the patient was allowed 1000 cc of fluids. After this time, urinary suppression caused no further concern so that by November 9, his output was 1250 cc and for the first time exceeded his intake (figure 1). During the period of urinary suppression and forced fluids, there was no edema and the feces were large, soft, and not increased in number.

About November 1, there was a distinctly palpable mass in the right upper quadrant of the abdomen. This was considered to be the right kidney by most observers, although a surgical consultant considered that an upper abdominal malignant growth, particularly carcinoma of the proximal portion of the transverse

colon, should be considered. This mass remained palpable for about one month. A cystoscopic examination showed a pelvic deformity of both kidneys which very strongly suggested polycystic disease (figure 2). Because of the roentgen findings simulating polycystic disease of the kidneys and because one kidney was palpable, the diagnosis of renal amyloidosis or chronic glomerulo-nephritis, with nephrotic component, was changed to polycystic disease of the kidneys.

On November 27, the patient developed an acute, non-contagious parotitis on the right side. This was accompanied by fever, elevation of pulse rate, and toxemia.

FIG 1 Chart of the patient's intake and output showing the change after the Karell diet

Four days prior, the first evidence of edema in the ankles was noted, but diminished on a salt free diet. On December 7, the parotid swelling had greatly diminished and soon disappeared. The blood pressure was 150 systolic and 96 diastolic. The right kidney, which could be felt as low as the umbilicus a month previously, had greatly diminished in size.

On November 18, an intravenous phenolsulphonephthalein showed no dye excretion within two hours. This was repeated on November 26 with the same result. On November 28, the blood urea nitrogen was 49.6 mg and the creatinine 3.0 mg per cent.

On January 3, 1935, the hemoglobin was 50 per cent, Sahli, in contrast to 75 per cent on entry. The blood urea nitrogen was 50.7 mg per cent. The patient was put on 0.5 gram of reduced iron three times a day. On February 16, the hemoglobin had increased to 72 per cent and one month later, with the patient near death, it was 62 per cent although iron had been discontinued for two weeks.

FIG 2 Retrograde pyelogram showing the widened and elongated renal pelves and calices suggesting polycystic disease of the kidneys

Edema became a troublesome and an increasing feature of the patient's illness after February 14. On March 5, stool specimens contained large amounts of red blood. On March 13, the blood pressure was 180 systolic and 110 diastolic. Urinalysis showed specific gravity 1.009, albumin trace, white blood cells 8-10 per high power field. On March 24, he began to vomit bright red blood and continued to do so for several days. His edema became more marked, and there was a gradual rise

of the blood urea nitrogen (highest 59.3 mg per cent) Marked fatigue, vomiting, and signs of uremia increased until April 15, 1935 when death occurred

Autopsy Report Postmortem examination revealed a marked generalized edema, a non-tuberculous fibrinous pericarditis, and a decubital ulcer over the sacrum

The lungs contained numerous irregularly scattered, healed, calcified nodules varying in size from 2 to 6 mm The apices were puckered and fibrotic Three thin

FIG 3 Photograph of the right kidney showing the enlarged pelvis and the narrowing of the renal cortex The shape of kidney pelvis and the narrowing of the renal cortex are evident

walled cavities, each 7 mm in diameter, were situated in the left apex, these were filled with thick white pus in which no organisms were found

The spleen weighed 112 grams, the liver 1500 grams They showed no evidence of disease The right kidney was situated 8 cm lower than the left and the ureter was correspondingly shorter The right kidney weighed 85 grams, the left 95 grams The parenchyma was firm, waxy, and the distinction between the cortex and medulla had almost disappeared The pelves, although not distended, appeared larger than normal and extended nearer the poles of the kidneys than is usual (Figure 3)

Microscopic examination In the left lung there are several minute calcified nodules surrounded by giant and epithelioid cells and lymphocytes. The cavity walls show a similar activity.

FIG 4 Microphotograph. The glomeruli are almost occluded by amyloid. The tubules are atrophic and frequently have marked deposits of amyloid.

The pericardium appears acutely inflamed. There is a fibrinous exudate on the surface, and the membranes are infiltrated with polymorphonuclear neutrophils. The small blood vessels of the liver and spleen appear slightly thickened. The

media contains a slight amount of amyloid. The hepatic parenchyma is slightly fatty but otherwise shows no evidence of disease. The malpighian corpuscles of the spleen occasionally contain a slight deposit of amyloid.

The renal glomeruli are occasionally normal in size, but usually they are small and contracted. Each glomerulus appears to be filled with amyloid. Few capillaries containing blood are demonstrable. The remnants of the tubules appear as thin tubes of amyloid with casts and some desquamated epithelium in the lumina. (Figure 4)

DISCUSSION

This case represents one in which the amyloid disease is almost wholly confined to the kidneys. It is unusual, for that reason, and also for the fact that it did not have the usual provocative causes so often associated with amyloid disease. It is true that the patient had pulmonary tuberculosis and was confined to the Sanatorium for two and one-half years (1921-1924). Yet, from 1924 until the time of his death, he was examined from two to four times a year, both by physical and roentgen examination, and there was no evidence of activation of his pulmonary tuberculosis. The first sign of amyloid disease appeared during this period of inactivity of his tuberculosis (1927). He did have suppuration of the right cervical glands two years prior to death. This lasted only four months and was considered tuberculous even though this could not be proved either by direct smear or guinea pig inoculation. But since this suppuration did not appear until five years after his first urinary findings, it cannot therefore be considered a predisposing factor.

The limitation of the amyloidosis to the kidneys is quite uncommon. In Bell's series of 65 cases, only two had the amyloid confined to these organs. Raubitschek found only two cases in a series of 72, in which the liver and spleen were not involved. In our own series of 109 cases, the kidneys were the almost exclusive sites of deposit in only this one instance. Since the publication of Bell's paper in 1933, amyloidosis involving the kidneys alone has been reported by Rosenblatt (2) and Perla and Gross (2).

In every instance in Bell's series of 33 cases with tuberculosis, there was extensive chronic suppuration. In our case the suppuration was present in the form of minute cavities, but these were so small that it seems unlikely they would cause the changes which led to death. They could not be seen on roentgen examination. The pulmonary tuberculosis was certainly inactive until the terminal stages. The cavities gave no symptoms whatever, and each of the three cavities was only 7 mm in diameter.

Death from amyloid disease by uremia, although quite rare, is probably more common than is generally supposed. Perla and Gross go so far as to state that "Uremia complicating amyloidosis of the kidney has been observed not infrequently." Bell found only 10 cases reported before 1933, and since that time there are only nine reported by the following: Dixon (1), Perla and Gross (2), Carey (1), Willer (2), Fahr (1), Langeion et al (1), and Mahoudeau et al (1).

The roentgen picture of the kidney is unique. We have been unable to find another case in which the pelves were so deformed as to give the appearance of large kidneys. Moreover, the presence of large and a somewhat irregular mass detectable on casual palpation seemed to lend confirmation to the diagnosis of polycystic kidney. The presence of a mass in the right upper quad-

rant can be accounted for by the low position of the right kidney, but the apparent decrease in size still lacks a satisfactory explanation

SUMMARY

1 At the time of onset of the renal amyloidosis, the patient had arrested pulmonary tuberculosis with no extra-pulmonary complications. His early history, however, revealed two conditions found in association with amyloid, namely, adenitis and enteritis.

2 The patient's intake and output over a period of observation, illustrates a paradoxical diuretic response to the forcing and probably to the limitation of fluid intake, and the diuretic effect of concentrated dextrose given by vein and skimmed milk administered according to Karell procedure in urinary suppression.

3 The presence of a mass in the right upper quadrant and the roentgen findings of the renal pelvis led to an erroneous diagnosis of bilateral polycystic kidney.

4 The patient died in uremia due to renal amyloidosis.

5 Unusual also was the recovery from non-contagious parotitis and the unexpected response to the administration of iron in the marked anemia accompanying renal insufficiency.

EDITORIAL

VIRUS TUMORS

The volume and the highly specialized character of investigative work on the nature of malignant growths has to some extent rendered this field of medicine an obscure one for physicians. Certain recent advances in our knowledge of tumor producing agents may well have escaped general recognition.

In the early years of this century the possibility of the transmission of certain spontaneous new growths of animals to others of the same species by inoculation of bits of tumor tissue gained acceptance. Jensen in 1902 through his careful studies of the transmission of a spontaneous carcinoma of a white mouse helped greatly clearly to define the conditions necessary for the success of such inoculations. In the course of his investigations, he studied the behavior of the fragment of implanted growth. It was his purpose to determine whether the tumor that resulted arose from the tumor cells that had been injected, or from the cells of the host's tissues. By histological study of different stages, he concluded that whereas the central portion of the implant underwent necrosis, the marginal cells multiplied and formed the new growth. This indicated that these tumors were in a sense tissue cultures *in vivo* and that by repeating transfers, one was carrying on indefinitely the same race of cells. This conclusion of Jensen's accorded well with the studies of the period which had failed to disclose in neoplasms any extracellular infective agent which could be considered causative. It seemed to place the tumor cell itself in the position of being the ultimate carrier of the disease. The search for bacteria, fungi, or protozoa which could cause cancer remained fruitless, and infection as a cause for neoplasms appeared less and less likely.

The nature of irritants which acted as a factor in stimulating neoplastic growth came to be the central problem of cancer research on etiology and, especially since the discovery of coal tar cancer in animals by Yamagiwa and Itchikawa in 1915, this subject of chemical carcinogenic agents has been most intensively investigated.

In 1911, however, the theory of infection as a cause for neoplasms was rejuvenated by the publication of Peyton Rous' discovery of a chicken tumor which could be transmitted by a cell free filtrate of the tumor tissue. The widespread confirmation of this work and its further extension to certain other tumors of fowls proved conclusively that, in the case of these neoplasms at least, some other agent than the living tumor cell could transmit the neoplasm to closely related animals of the same species. Moreover, the growths incited in the host's tissues by the injection of the tumor filtrate were sufficiently similar to indicate a tissue specificity of the tumor-producing effect.

The nature of the agent in the tumor filtrate is still unknown in spite of intensive study of the problem. Many of its attributes, however, have been determined. It is invisible, it is filtrable, it is about 100 M μ in size, it is dependent for increase upon association with living cells, it induces the formation of neutralizing antibodies which act upon it *in vitro* but from which it is protected *in vivo* by its association with cells, it causes morbid changes in cells and induces proliferation to cause neoplasms. The growth of knowledge concerning virus diseases has shown that such are the attributes of certain types of viruses. As Rous has recently succinctly stated: "A comparison makes plain that the agents must be termed viruses or else that the criteria must be rejected whereby the latter are now recognized as such."

The classification of the agent as a virus does not of course settle the matter as to whether it is to be considered as living matter or an inanimate stimulus. This fundamental question is still an open one for all the viruses.

More vital is it to know how large a part viruses, whatever their ultimate nature, may play in the genesis of tumors. For many years their importance seemed relatively circumscribed, since no virus tumor of mammals had been observed. However, recently a virus-induced papilloma of wild rabbits has been described by Shope and intensively studied by Rous and others. A filtrate of this tumor was found to cause abundant warty growth when rubbed on the abraded skin of the domestic rabbit. In this animal the growth did not always retain the characteristics of a benign papilloma but instead developed typical cancerous growths with not infrequent metastases to regional glands and to the lungs. The virus can not be demonstrated in extracts of these cancers. The question therefore arises whether the cancerous transformation is due to the virus or to some further cause acting upon the virus induced papilloma. Rous notes, however, that in certain instances he has transferred cancer tissue from a metastasis of the original growth to the tissues of another rabbit and that with the growth of this implant this second animal developed in its blood neutralizing antibodies for the original virus. This speaks at least for the continued presence of the virus in the malignant stage of the growth.

The production of cancerous growths in a mammal by means of a virus will stimulate even greater interest in this type of carcinogenesis. The determination of the ultimate significance of viruses in the etiology of cancer must await, however, the results of many future investigations.

REVIEWS

Eugenical Sterilization By The Committee of the American Neurological Association for the Investigation of Eugenical Sterilization 211 pages, 22 × 15 cm The Macmillan Company, New York City 1936 Price, \$3 00

This book is the published report of a special committee of the American Neurological Society. The report first presents a brief history of legal sterilization and then a summary of the existing laws in the United States and in foreign countries. A critical review follows of the main arguments for sterilization, the reputed increase of insanity and defective mentality, the reputed increased propagation rate of the mentally diseased or defective, and the inheritability of mental diseases. The available data are shown to render questionable the validity of these assumptions unless in greatly qualified form. The Committee felt it could only recommend sterilization in selected cases of certain diseases and then only with the consent of the patient or those responsible for him. This book is a valuable corrective to much loose thinking and writing on this subject.

M C P

Failure of the Circulation By TINSLEY RANDOLPH HARRISON, M D 396 pages, 23 × 15½ cm The Williams & Wilkins Company, Baltimore Maryland 1935 Price, \$4 50

Students of the pathologic physiology of the circulation have followed with interest the investigations of Dr. Harrison and his colleagues at Vanderbilt University. In this volume a point of view attained by this group as to the meaning and mechanism of congestive heart failure is ably presented. No attempt is made to minimize the uncertainty still prevailing as to the nature of certain phenomena but from the existing data a strong argument is drawn that backward failure, or back pressure from the left and the right ventricles is the source of the congestive process. Diminished cardiac output is shown to be often present in conditions unaccompanied by evidence of congestive failure and to be often absent in typical instances of congestive failure. Hence it is argued "forward failure," or diminished output, cannot explain congestive failure. The discussion of the significance of cardiac dilatation and hypertrophy is of particular interest.

The sections dealing with failure of the "shock" type and failure through coronary disease seem much less adequate than the main section of the book. The inclusion under coronary disease of purely clinical description and of therapeutic recommendations does not seem in keeping with the purpose of the volume.

The frank espousal of a theory is much more stimulating than the mere presentation of a mass of data. The book should interest every thoughtful clinician.

M C P

An Index of Treatment By various writers, edited by ROBERT HUTCHINSON, M D, LL D, F R C P Eleventh Edition, Revised Super Roy 8 10 1020 pages, 18 × 26 cm Wm. Wood and Co., Baltimore 1936 Price, \$12 00

This work is a companion volume accompanying texts on Symptomatology, Diagnosis, and Prognosis. It attempts to cover within the space of a thousand pages the therapy of practically every medical and surgical condition on record. Obviously such discussion must be brief.

To the reviewer it seems neither wise nor practical to present the operative therapy of acute appendicitis, together with the management of its complications.

and after-treatment, within the space of two pages. In the hands of one in need of such information, it might be more dangerous than helpful. The same comment might be offered concerning many of the operative procedures described—none of which should be attempted without a background of surgical experience which would render such discussion unnecessary.

While the medical topics discussed are not subject to the above criticisms, they are of necessity brief. Many methods are mentioned which may rightly be considered outmoded—the use of leeches, for example, as recommended for relief of pleuritic pain in pneumonia, and precordial pain in acute rheumatic carditis. The section on poisons might be of convenience for ready reference. The discussion of hypnotism would seem of little value to the average reader of the volume. The method of antiluetic therapy advised is not adequate according to the standards established in this country, and adherence to it might give rise to dangerous end-results.

In our opinion this volume cannot be said to fulfill satisfactorily the implications of its title.

COLLEGE NEWS NOTES

NOMINATIONS, 1937-38

Elective Offices

Dr James H Means, President-Elect, Boston, Mass, accedes to the Presidency

New Nominations

President-Elect	William J Kerr, San Francisco, Calif
First Vice-President	David P Barr, St Louis, Mo
Second Vice-President	G Gill Richards, Salt Lake City, Utah
Third Vice-President	William Gerry Morgan, Washington, D C

Respectfully submitted,

Committee on Nominations,

WILLIAM B BREED

JAMES D BRUCE

CHARLES T STONT

CHARLES F MARTIN

GEORGE MORRIS PIERSOL, *Chairman*

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following gifts by the authors to the College Library of publications by members

Books

Dr Howard T Karsner (Fellow), Cleveland, Ohio—one autographed book, "Human Pathology," Fourth Edition,
Dr W McKim Marriott (Fellow—Deceased), San Francisco—one book, "Infant Nutrition",
Dr F M Pottenger (Fellow), Monrovia, Calif—one autographed book, "Tuberculosis in the Child and the Adult",
Dr Paul D White (Fellow), Boston, Mass—One autographed book, "Heart Disease," Second Edition,
Dr Clarence J Tidmarsh (Associate), Montreal, Que—one book, "Chronic Indigestion"

Reprints

Dr William E Ash (Fellow), Council Bluffs, Iowa—1 reprint,
Dr John L Goforth (Fellow), Dallas, Tex—1 reprint,
Dr William A Groat (Fellow), Syracuse, N Y—1 reprint,
Dr Manfred Kraemer (Fellow), Newark N J—1 reprint,
Dr D O N Lindberg (Fellow), Decatur, Ill—1 reprint,
Dr Harry R Litchfield, Brooklyn, N Y—1 reprint,
Dr Fred M Meixner (Fellow), Peoria, Ill—1 reprint,
Dr George R Minot (Fellow), Boston, Mass—2 reprints,
Dr Edgar A Hines, Jr (Associate), Rochester, Minn—4 reprints,
Dr Maurice S Jacobs (Associate), Philadelphia, Pa—5 reprints,
Dr Leslie M Smith (Associate), El Paso, Texas—3 reprints

We also gratefully acknowledge the gift of the following books to the College Library by the author, Dr Charles Solomon, Brooklyn "Pharmacology, Materia Medica and Therapeutics", "Prescription Writing and Formulary"

NEW LIFE MEMBERS

The following have become Life Members of the American College of Physicians at the dates indicated, making a total of seventy-seven Life Members

Dr Samuel A Vogel, Buffalo, N Y, January 25, 1937,
 Dr Mills Sturtevant, New York, N Y, February 4, 1937,
 Dr Russell M Wilder, Rochester, Minn, February 5, 1937

ANNUAL MEETING OF THE NEBRASKA MEMBERS OF THE COLLEGE

The Nebraska College Meeting was held January 13, Lincoln, Nebraska, Hotel Cornhusker

A scientific program was held during the afternoon, which was followed by a banquet at 6 00 pm A short business session followed the dinner and then the scientific program was continued It was a very enthusiastic meeting and it was decided that the next meeting would be held in Omaha

Afternoon Program Dr J C Thompson (Fellow), "Desiccated Duodenal Mucosa in the Treatment of Anemia", Dr J Marshall Neely (Fellow), "The Pathogenesis of Tuberculous Meningitis", Dr H E Flansburg (Fellow), "Report of an Atypical Case of Pulmonary Congestion Due to Congestive Failure", Dr H J Lehnhoff, "Report on Cases of Simon's Disease", Dr F L Rogers (Fellow) and Dr G W Covey (Fellow), "Report of a Case of Thymoma with Cardiac Metastasis", Dr Edward Meister, "Report of Case of Coarctation of the Aorta" Dr E H Hashinger (Associate), Kansas City, Mo, was the guest speaker of the evening and discussed "The Practical Side of Endocrine Therapy"

ADOLPH SACHS, M D, F A C P,
 Governor for Nebraska

MEETING OF THE AMERICAN BOARD OF INTERNAL MEDICINE

The Chairman of the American Board of Internal Medicine, Dr Walter L Biering, has reported a meeting of the Board at Chicago, February 13, 14 and 15, 1937 A report on the candidates who took the Board's written examination, December 14, 1936, reveals that forty-eight candidates were passed and eight were recommended to repeat the examination in October, 1937 The next written examination is scheduled for March 22, 1937 The first practical or clinical examination will be conducted on Friday, April 23, at the City Hospital, St Louis, Mo, beginning at 9 00 a m, this being the closing day of the Twenty-First Annual Session of the American College of Physicians at St Louis The second practical examination will be conducted by members of the Board on Saturday, June 5, 1937, in Philadelphia

ANNUAL CONGRESS ON MEDICAL EDUCATION AND LICENSURE

The Thirty-Third Annual Congress on Medical Education and Licensure was held in Chicago, February 15 to 16, 1937 Among Fellows of the College who participated are the following

Dr William D Cutter, Chicago, Ill, "Report of the Survey to Individual Schools",
 Dr R L Sensenich, South Bend, Ind, "The Doctor and the Narcotic Violator",

- Dr Torald Sollmann, Cleveland, Ohio, "The Why, What and How of the Medical Scholastic Aptitude Test",
Dr Howard T Karsner, Cleveland, Ohio, "Philosophical Comments on Examinations",
Dr Harold Rypins, Albany, N Y, "Increase in the Number of Practitioners in the Country",
Dr Joseph C Doane, Philadelphia, Pa, "How Nursing May Promote Inter-Professional Relationships"
-

Dr F H Voss (Fellow), Kingston, N Y, has been elected President of the Ulster County Medical Society for 1937 Dr Voss also has been appointed by the Mayor as a member of the Board of Managers of the Kingston City Laboratory for a period of three years

Dr William C Voorsanger (Fellow), San Francisco, delivered the third Lane Popular Medical Lecture February 5, 1937, under the auspices of the Stanford University School of Medicine, his subject being "Recent Advances in the Treatment of Tuberculosis"

Dr L D Sargent (Fellow), Washington, Pa, has been elected a Trustee of the Pennsylvania State Medical Society and Councilor of the Eleventh District

Dr Fred M Meixner (Fellow), Peoria, Ill, has been reelected President of the Peoria County Tuberculosis Association Dr Meixner is a Director of the Illinois State Tuberculosis Association and also a member of a special committee, of which Dr Maxim Pollock (Fellow), Peoria, is chairman, to plan a tuberculosis survey in the schools of the City of Peoria

Dr John C Ruddock (Fellow) and Dr Howard F West (Fellow), both of Los Angeles, have been made President and Secretary-Treasurer, respectively, of the newly organized California Heart Association

The First New Orleans Graduate Medical Assembly was held March 8-11, with a program of clinical demonstrations, didactic lectures, round table discussions and symposia Among Fellows of the College outside of New Orleans who contributed to the program were Dr Anthony Bassler, New York City, Dr Russell Cecil, New York City, Dr John A Kolmer, Philadelphia, Dr Julius H Hess, Chicago, and Dr George Morris Piersol, Philadelphia

Dr Louis P Hamburger (Fellow), Associate in Medicine, Johns Hopkins University School of Medicine, has been appointed consultant to the Baltimore City Health Department

Dr Thomas Hodge McGavack (Associate), formerly of San Francisco, has been appointed Associate Professor of Medicine at the New York Medical College and Flower Hospital

Dr J Arthur Myers (Fellow), Minneapolis, addressed the forty-fifth annual meeting of the Pennsylvania Tuberculosis Society in Philadelphia on January 20

Dr J Burns Amberson, Jr (Fellow), has been promoted to Professor of Clinical Medicine on the Faculty of New York University College of Medicine

Dr Elmer L Sevringhaus (Fellow), Madison, Wis, and Dr Francis E Senear (Fellow), Chicago, were among those who appeared on the program of the ninth spring clinical conference of the Dallas Southern Clinical Society, March 15 to 18

A Pneumonia Commission has been appointed by the President of the Medical Society of Virginia, Dr J Morrison Hutcheson (Fellow), Richmond, to investigate the incidence and types of the disease in Virginia and the kind of management in vogue. Members of the Commission include Dr Wyndham B Blanton (Fellow), Richmond, chairman, Dr Walter B Martin (Fellow), Norfolk, Dr Henry B Mulholland (Fellow), Charlottesville, Dr Philip S Smith (Fellow), Abingdon, and Dr Harry Walker (Associate), Richmond

Dr Milton M Portis (Fellow), Chicago, is a member of the professional committee for medicine in the Illinois State Department of Registration and Education

Dr James H Means (Fellow and President-Elect), Boston, addressed the North Side Branch of the Chicago Medical Society, February 4, on "The Rôle of the Physician in the Management of the Patient with Thyrotoxicosis"

Honorary fellowship in the Royal College of Physicians and Surgeons (Canada) was recently conferred upon Dr Henry A Christian (Fellow), Boston, Mass

Dr Cyrus C Sturgis (Fellow), Ann Arbor, Mich, Dr Andrew C Ivy (Fellow), Chicago, and Dr Jonathan C Meakins (Fellow), Montreal, were among the guest speakers at the fifty-third annual meeting of the Mid-South Post Graduate Medical Assembly, held at Memphis, Tenn, February 16 to 19

Dr Carl J Wiggers (Fellow), Professor of Physiology, Western Reserve University School of Medicine, Cleveland, Ohio, is on sabbatical leave, while on a trip around the world

The Medical Society of the State of Pennsylvania has established a commission for the study of pneumonia control. Among the members of the commission are Drs Edward L Bortz (Fellow), Philadelphia, chairman, Edward W Bixby (Associate), Wilkes-Barre, George J Kastlin (Fellow) and Clifford C Hartman (Fellow), Pittsburgh, T Grier Miller (Fellow), Henry K Mohler (Fellow) and Leon H Collins, Jr (Associate), Philadelphia

Dr Thomas Klein (Fellow) has been appointed Professor of Clinical Medicine at Temple University School of Medicine, Philadelphia

Dr Samuel B Hadden (Fellow) has been promoted to Clinical Professor of Neurology at Temple University School of Medicine, Philadelphia

Dr Thomas Parran (Fellow), Surgeon General of the U S Public Health Service, was one of the principal speakers at the laying of the cornerstone of the U S Narcotic Farm at Fort Worth, Texas, February 13. This is the second narcotic farm to be built by the U S Public Health Service under the jurisdiction of the division of mental hygiene. The first was opened during May, 1935, at Lexington, Ky, where 1,240 patients were admitted during the first year of operation. The annual report of the Public Health Service states "There is no question that the treatment of narcotic addiction in a hospital has distinct advantages over the management of such cases in a correctional institution."

Dr Fred E Clow (Fellow), Wolfeboro, N H, was elected Secretary-Treasurer of the State Board of Registration in Medicine

Dr Josiah N Hall (Fellow), Emeritus Professor of Medicine, University of Colorado School of Medicine, Denver, and a former Governor of the College for Colorado, was the guest of honor at a testimonial dinner, February 20, given by Dr Hubert Work (Fellow), formerly Secretary of the Interior Dr Hall has retired from active practice as of March 1 He is seventy-seven years of age, a native of Chelsea, Mass, and a graduate of Harvard University Medical School, 1882 His medical career has been rich in experience and service He has contributed much, has sown well, his harvest is one of many honors, of love and of appreciation Tribute was paid him in 1936 by the Colorado State Medical Society when the banquet and president's reception were dedicated to him in recognition of his fiftieth year of attendance at the annual sessions of that Society

Dr George W McCoy (Fellow), who since 1915 has been director of the National Institute of Health, formerly known as the "Hygienic Laboratory," has been relieved of this appointment to make investigations on leprosy Dr McCoy is a native of Cumberland Valley, Pa, is sixty years of age and a graduate of the University of Pennsylvania School of Medicine, 1898 He entered the Public Health and Marine Hospital Service in 1905 as assistant surgeon, in 1913 he became surgeon in the U S Public Health Service He was named medical director July 1, 1930 From 1908 to 1911 he was in charge of the U S Plague Laboratory, San Francisco, and from 1911 to 1915 director of the U S Leprosy Station, concurrently serving during this period as sanitary adviser to the Hawaiian Government He has written numerous papers on public health and bacteriological subjects He was President of the Washington Academy of Sciences during 1935

Dr Thomas Parran (Fellow), Surgeon General of the U S Public Health Service, Washington, received the honorary degree of Doctor of Pharmacy at the 116th annual celebration of Founders' Day at the Philadelphia College of Pharmacy and Science on February 23 Dr Parran delivered an address, "The Aims and Ideals of the United States Public Health Service"

ERRATUM

In the College News Notes of the January 1937 issue, page 1071, of the Annals of Internal Medicine, announcement was made that Dr Elliott P Joslin of Boston is President of the Interstate Post-Graduate Medical Association Dr Joslin is President-Elect at the present time, Dr John F Erdmann of New York City is President

OBITUARIES

DR LUTHER FISKE WARREN

Dr Luther Fiske Warren was born in Waterford, Michigan, September 20, 1885, the son of Charles B Warren and Anna Weinmann. He died on January 18, 1937, at his home, 81 Pierrepont Street, Brooklyn, after a long period of intense suffering, of generalized metastases resulting from a mammary gland carcinoma removed several years previously. He is survived by his widow, his mother, his two sons, Dr Charles Ford and Dr Robert Fiske, both connected with the Long Island College Hospital, a daughter, Miss Edith Warren, and a brother and sister.

From earliest childhood Dr Warren began to exhibit his enormous capacity for work. As a small child he worked on the farm, while attending the local school. Going to Ann Arbor in order to complete the last two years of high school there, he began to shift for himself, working his way successively through the literary and medical schools of the University of Michigan. As a Freshman in the literary school he married Miss Agnes Chubb, a student in the dental school, and before he had finished his medical course his wife had borne him two children, and had had an operation for gall-stones. In spite of the cares connected with providing for this family, in his junior year in medical school he was elected to the honorary fraternity, Alpha Omega Alpha, and in his senior year to Sigma Xi. He received the degree of A B in 1907 and M D in 1909. Following his graduation from medical school he was kept on as Instructor in Medicine, teaching physical diagnosis and giving the first course in clinical microscopy ever given at the School. As a result, even though so young, he was frequently called in consultation by older physicians in Ann Arbor. During the three years of this work his daughter was born.

In 1912 Dr Warren was called to the Long Island College Hospital, Brooklyn, to be director of the newly established clinical laboratories, with the title of Assistant Professor of Clinical Medicine. His prodigious energy and remarkable teaching ability resulted in rapid promotion. From 1915 to 1917 he was Associate Professor of Medicine, from 1917-1919, Acting Professor of Medicine, and in 1919 was made Professor of Medicine. With the reorganization of the College in 1930, he became Professor of Medicine of the Long Island College of Medicine, a post he was holding at his death. He also held many other medical appointments in Brooklyn, being Physician-in-Chief at the Long Island College Hospital and St Johns Hospital, Medical Director of the Brooklyn Home for Consumptives, which he completely reorganized after his appointment in 1931, and Consulting Physician to the Methodist Episcopal, Coney Island, Harbor, Lutheran, Southside and Brunswick General Hospitals.

DR LUTHER F WARREN
REGENT OF THE AMERICAN COLLEGE OF PHYSICIANS

Dr Warren's medical society memberships were very extensive and he held many official positions in them. A Fellow of the American College of Physicians since 1919, he was Governor from 1931 to 1933 and a Regent from 1933 until his death. He served on many committees, giving most of his time and service to the Committee on Credentials. He was an advisor to the American Board of Internal Medicine. Memberships in national societies included the American Medical Association, American Heart Association, National Tuberculosis Association, Association for Study of Internal Secretions, American Society of Tropical Medicine, American Society for the Advancement of Science. Local societies included the New York Academy of Medicine, Medical Society of the County of Kings (President, 1930), Brooklyn Society of Internal Medicine, Brooklyn Pathological Society, Brooklyn Medical Association and Associated Physicians of Long Island. He was Chairman of the Public Relations Committee of the Medical Society of the State of New York. In addition to the enormous amount of time spent in teaching, in administration of his departments in the medical school and hospital and in his medical society activities, Dr Warren was an examiner in diagnosis of the New York State Board of Medical Examiners from 1933 until his death, and was an active participant in the activities of many civic and educational organizations. He was a member of the Board of Trustees of Polytechnic Institute and of the Packer Collegiate Institute, a member of the Board of Directors of the Brooklyn Chamber of Commerce and Chairman of its Public Health Committee, President of the Brooklyn Health Council and Member of Board of Directors of the Brooklyn Council for Social Planning.

From 1911 onward Dr Warren began to contribute to medical literature, his early works being devoted to clinical laboratory methods. He contributed a Section on Diseases of the Bronchi to Tice's Practice of Medicine and was Medical Editor of the International Medical Digest from 1920 to 1928. He was frequently called upon to speak or to discuss papers at medical meetings and always gave freely of his knowledge.

On reading of the foregoing list of activities of this remarkable man, one would conclude that here was a full-time professor in the medical school, with nothing to do but to teach, to administer his departments and to attend meetings. But this was decidedly not the case with Dr Warren. His private practice was one of the largest in Brooklyn, and no one was called upon more for consultation work. He was worshiped by his students, and when they entered practice they constantly sought his help in difficult cases. He reported at the hospital at 8:30 every morning, worked all day and evening, and would often say that his only time for study and for preparation for his day's work would be between 12:00 and 3:00 a.m. Although slight of build he was a man of iron. His muscles were like whip-cords. He gloried in his farm at Brewster, New York, where he experimented with

DR FRANK SMITHIES
MASTER OF THE AMERICAN COLLEGE OF PHYSICIANS

intensive production of crops and animals. He was a loving husband and father, taking particular delight in recounting the events of his children's educational and developmental life. He and Mrs. Warren were genial hosts and entered much into the social activities of Brooklyn. His daughter's debut was an event of importance in the city's social life.

Those associated with Dr. Warren in his many activities knew him as a man with high ideals, whose large brown eyes would glow and whose firm jaw would set with determination when he was advocating a measure which he considered to be right, or opposing one which he felt would be inadvisable or unjust. He not only worked hard himself, but had the faculty of making others exert themselves to the utmost, so that he lived constantly in an atmosphere of intense activity. It is no wonder that his life should have been ended so soon. He compressed a maximum of living into his 51 years of life.

A. F. R. ANDRESEN, M.D., F.A.C.P.

DR. FRANK SMITHIES

Dr. Frank Smithies (Master) passed away Tuesday morning, February 9, 1937, following a cerebral hemorrhage.

He was born in Elland, England, December 21, 1880, and came to the United States when a very young child and had his elementary school education in Philadelphia and Chicago. He was a graduate of the Calumet High School of Chicago and studied medicine at the University of Michigan, from which school he was graduated in 1904. Following this he went abroad and studied at the University of Berlin and Guy's Hospital, London.

After returning to this country he taught at the Rush Medical College 1904-05, and then at the University of Michigan, 1906-10. He then went to the Mayo Clinic, Rochester, Minn., where he was gastro-enterologist from 1911-14. After this he removed to Chicago, where he practiced diagnostic medicine with especial reference to diseases of the digestive system. From 1915 to 1925 he was professor of medicine at the University of Illinois. He was Attending Physician, Henrotin Hospital, since 1921, Chief of Clinic in Digestive Diseases, Municipal Tuberculosis Sanitarium, Chicago, 1927-30, Consulting Physician of the C. M. & St. P. R. R.

He made many contributions to the medical literature. His papers numbered well over one hundred, including his book on Cancer of the Stomach, published in 1916. He was Editor-in-Chief of the *American Journal of Digestive Diseases and Nutrition*, and Associate Editor of the *American Journal of Syphilis* (St. Louis) and *American Journal of Tropical Medicine* (Baltimore). He was the first Editor of the *Annals of Clinical Medicine*, official journal of the American College of Physicians.

He was past president of the following societies American College of Physicians, 1927-28, American Gastro-Enterological Association, 1929-30, American Society of Tropical Medicine, 1931-32, American Therapeutic Society, 1932-33

His hobbies were reading and fishing He collected many rare books and was particularly interested in books on arctic explorations of which he had an unusually large collection

In 1917 he was made a Fellow of the American College of Physicians, and elected a member of its Council later in the same year In 1918, together with a group of prominent Internists throughout the country, the reorganization of the American College of Physicians was undertaken, with Dr Smithies as Secretary General The rapid advancement of the College from that time on was recognized as due, to a large extent, to the forceful presentation by Dr Smithies of the great need for the organization by the Internists of America He introduced the clinical character of its annual meetings, stimulating great interest in these gatherings In recognition of service to the College, he was made one of the six Masters of the society, he being the fourth of these to pass away He was liaison representative of French and American Medicine in this Country, and was made a Chevalier of the Legion of Honor of France

A great soul has gone from us Frank Smithies is no longer with us In our hearts and minds we realize that we have sustained a major loss, the magnitude of which grows as we contemplate his achievements, his capacity of analytical ingenuity, his editorial versatility, his differential judgment, an outstanding gift of sympathetic understanding as well as a prophetic vision of the future of Internal Medicine His virile spirit enabled him to surmount difficulties which would have halted less courageous souls

CLEMENT R JONES, M D , F A C P

DR LOUIS HENRY FALES

Dr Louis Henry Fales (Fellow), Livermore, Calif, died February 13, 1937, at Fort Miley, San Francisco, of anemia

Dr Fales was born at Janesville, Wis, October 7, 1871 He received the degree of Bachelor of Laws from the University of Wisconsin in 1893 and the degree of Doctor of Medicine from Rush Medical College, Chicago, in 1897 He interned at St Luke's Hospital, Chicago, 1897-99 He was Physician-in-Charge of the Bilibid Prison Hospital, Manila, P I, 1901-03, Physician-in-Charge, Baguia Sanitarium, Baguia, P I, 1903-04, in 1918 he was commissioned Captain in the Medical Corps of the U S Army, and was discharged in 1920 He also held a commission as past assistant surgeon in the U S Public Health Service and assigned to active duty in 1920

He was commissioned surgeon in this Service in 1920. In 1924 he transferred to the U S Veterans Bureau. He served as ward surgeon and acting clinical director of the Veterans Administration Hospital at Palo Alto, Calif, 1924-25, and as ward surgeon, acting clinical director, medical officer in temporary charge and acting roentgenologist at the Veterans Administration Hospital, Livermore, Calif, between 1925 and the date of his death. In his earlier work in the Philippine Islands he was a medical inspector with the Philippine Health and Sanitary Service, and had considerable experience with bubonic plague and cholera at that time.

Dr Fales was the author of a number of articles, appearing in leading medical journals. He was a past president of the Veterans Administration Facility Medical Society, a member of the Alameda County (Calif) Medical Society and a member of the American Tuberculosis Association. In the course of his work he pursued various postgraduate courses at the University of Wisconsin, the U S Army Medical School and the University of California Medical School, always seeking to keep himself well informed of medical progress. He had been a Fellow of the American College of Physicians since 1933.

DR WALTER OLIN NISBET

Walter Olin Nisbet, B S, M D, F A C P, died suddenly in Charlotte, North Carolina, his home, January 18, 1937.

He was born in Lancaster County, South Carolina, October 5, 1866, the son of Dr John Newton and Mary Jane Phifer Nisbet. He graduated at the University of South Carolina in 1885 with the B S degree, receiving his medical degree in 1889 from the Medical College of South Carolina in Charleston, serving his internship in the Roper Hospital in that city. He was a member of the S A E and O D K fraternities.

After ten years of general practice in Richburg, South Carolina, and Waxhaw, North Carolina, he spent a year in study in Berlin, preparatory to entering the field of gastroenterology, in which field he became recognized as one of the leading specialists of the South. He located in Charlotte, North Carolina, at this time, and was dean at the medical school there from 1912 to 1916. With others, he organized the Charlotte Sanatorium in 1909, and continued as a member of its staff as well as that of the Presbyterian Hospital until his retirement in 1934, two years after suffering a coronary occlusion.

Dr Nisbet was for twenty-five years an elder of the Second Presbyterian Church, and was a member of the Charlotte Country Club, his chief interest in sport being in hunting and golf. He was a member of his County and State Medical Societies, the Tri-State Medical Society, the Southern Medical

Association, the American Medical Association, and the Gorgas Memorial Institute of Tropical Medicine, and he became a Fellow of the American College of Physicians in 1923

His contributions in his chosen field were always well informed, illuminating, and authoritative. Ever alert to progress in his chosen line, he was particularly interested in the development and progress of his younger colleagues, all of whom as well as a host of friends throughout the South revere his memory. To them he was ever a source of comfort, strength, and friendly encouragement.

He is survived by his widow, the former Miss Eugenia Heath of Waxhaw, and three sons, Everett, Walter O. Jr., and Dr. Douglas Heath Nisbet, F.A.C.P., who was associated with him in practice for the past eighteen years.

CHARLES H. COCKE, M.D., F.A.C.P.,
Governor for North Carolina

DR. WILLIAM G. STEARNS

William Guilford Stearns was born at Lomax, Wisconsin, February 11, 1865.

He attended Northwestern University Medical School from which he was graduated in 1893. The following year he served an internship at St. Luke's Hospital in Chicago, and the next year acted as Assistant Physician at the Illinois State Hospital for the Insane at Kankakee, Illinois, he served for two years in the same institution as Pathologist and later was the Medical Superintendent for two years. He was Medical Superintendent of the Oakwood and Lake Side Sanatoria, Lake Geneva, Wisconsin, from 1900 to 1904, Professor of Pathology, Anatomy, and General Pathology at Northwestern Dental School, 1894 to 1898, and Assistant Professor of Mental Diseases and Medical Jurisprudence at Northwestern University Medical School, 1898 to 1900. Later he served as Lecturer in Neurology at the College of Physicians and Surgeons in Chicago, 1900 to 1902. In 1898 he was Chairman of the Section on Insanity, National Conference of Charities and Correction. He served with the Medical Advisory Board, Number 3E Selective Service, as a consultant in neuro-psychiatry, 1917 to 1919. He was Medical Director of the North Shore Health Resort, Winnetka, Illinois, 1931 to 1936.

Dr. Stearns was a member of Nu Sigma Nu and Alpha Omega Alpha fraternities. His society memberships included American Medico-Psychiatric Association, Central Neuro-Psychiatric Association, Chicago Medical Society, Illinois State Medical Society, Chicago Neurologic Society, Chicago Society for Prevention and Relief of Heart Disease, Fellow of the

American College of Physicians (1917), American Medical Association and Chicago Institute of Medicine

Dr Stearns was recognized as a member of the profession, highly regarded by his fellow practitioners. His friends in and about Chicago, both professional and others, were legion. He was a man of upright character, noted for his fairness, integrity and good judgment and widely known as a gentleman of fine character, and a physician of unusual talents. The profession in Chicago has lost a man who was an exemplar of a type of character which brings to our profession special regard. He will be sorely missed by those who have had the privilege of knowing him personally.

JAMES G. CARR, M.D., F.A.C.P.,
Governor for Northern Illinois

HISTORIC ST LOUIS

LONG ago the site of St. Louis was peopled by the Mound Builders, a prehistoric race which inhabited the Mississippi Valley. Little is known about them, but it is interesting to note that the ancient Toltecs of Mexico had legends that their nation originally lived in and was driven from a country far away to the northeast. In the collections of the Missouri Historical Society are strange relics of a civilization believed to antedate the Indians and to have represented a superior race.

St. Louis is sometimes called the "Mound City," from the many strange mounds discovered on its site. The largest of these was at what is now Mound Street, at the corner of Broadway. Others were in the present Forest Park. Seven miles east of the city is the famous Cahokia, or "Monk's Mound," said to be the greatest in the world. This mammoth of the group is larger than the greatest Egyptian Pyramid, and appears to be much older. It is an earth pyramid 1,080 feet long, 780 feet wide and 104 feet high, spreading its huge bulk over 15 acres of ground, with terraces at various levels.

The origin of these mounds has long been shrouded in mystery. Warren King Moorehead, Curator of the Museum of Phillips Andover Academy, several years ago made a series of careful excavations and for six weeks peered into the mysteries of these great earth piles, obtaining therefrom much scientific data. He found proof that they were deliberately fashioned by man. It is probable that they were once the site of an ancient city whose population ran into the thousands—perhaps 100,000 persons—who lived and toiled and disappeared long before the beginnings of American chronicles.

The founding of the present city must be attributed to a far-sighted French merchant, named Pierre Laclède Liguist, who conceived the idea of establishing a permanent settlement in some favorable location on the Mississippi. Accompanied by young Auguste Chouteau, he explored the river searching for an ideal spot. In December, as the still preserved record relates, "he fixed upon the place, marked with his own hands some trees and said to Chouteau, 'You will come here as soon as navigation opens and will cause this place to be cleared in order to form our settlement after the plan I shall give you,' and to DeNoyon, Commandant at Fort Des Chartres, he enthusiastically stated that he had found a situation where he was going to form a settlement which might become, hereafter, 'one of the finest cities in America—so many advantages were embraced in this site, by its locality and its central position for forming settlements'."

It was on the evening of February 14, 1764, that Chouteau and a band of thirty French pioneers landed on the west bank of the Mississippi River at what is now the foot of Walnut Street in St. Louis. For four long days they had poled and dragged their heavy craft from Fort Chartres, sixty

FIG 1 Old St Louis Cathedral

miles below Weaned by their labors, they slept that night in the boat On the following morning Chouteau led his men across the sandy beach, up to the plateau overlooking the river and pointed out to them the line of trees which he and Laclede had marked Thus began the building of St Louis

Those were pioneer days The entire upper Mississippi Valley was a silent wilderness Here and there, hundreds of miles apart, were roughly stockaded and scantily garrisoned forts and trading posts, constituting the meager outposts of civilization, the sole refuge against Indian attacks Life was a continued struggle for existence

Other expeditions, French and Spanish, soon sought to overshadow the little settlement of St Louis A Spanish Fort was built a short distance to the north Yet so well had Laclede chosen, and so energetically had his followers labored, that these competitive efforts gradually merged with St Louis itself Within three years its colonists had established valuable fur-trading monopolies with the 28 principal Indian nations, including not only those west of the Mississippi, but also east of the river and even as far north as the Great Lakes These the English tried in vain for many years to break

The fur trade was the commercial cornerstone of St Louis' prosperity Every year saw the city's sphere of influence broaden Up the Mississippi and Missouri crept a line of outposts St Louis became the gateway of a stream of migration, the starting point of expeditions in all directions, some military, some scientific, others to establish new communities or to open commercial avenues The greatest of these, the Lewis and Clark expedition, which was responsible for the opening of the Northwest, left St Louis in 1804 The Frenchmen of St Louis paved the way for the American occupation of Louisiana A branch of the Chouteaus started Kansas City Robidoux, of St Louis, established St Joseph One of the Menards founded Galveston A hundred western cities and towns owe their beginning to St Louisans

THE SIGHTS OF ST LOUIS

No visitor to St Louis should be at a loss as to what to do or what to see Members of the medical profession and their wives who visit St Louis in April will enjoy the Art Museum, the Cahokia Mounds, the Confederate Memorial, the Dent House, Forest Park, Grant's Log Cabin, the Jefferson Memorial, the Lindbergh Trophies, the Old Court House, the Mississippi River Front, Shaw's Gardens, St Louis Municipal Airport, the Zoological Gardens and many other attractions

The St Louis Zoo is worthy of special attention Feeding time in the midafternoon is an event of interest and pleasure for young and old The trained chimpanzees, the monkey kindergarten, the performing tigers and the hungry, barking sea lions constitute a show which will long be remembered The collection of reptiles, now housed in a new and beautiful build-

FIG 2 The Jefferson Memorial which houses the Records of the Missouri Historical Society and the Lindbergh trophies

ing, is outstanding. The cageless bear pits, which have attracted the notice of zoological experts from all over the world, are artificial rocky dens with earth filled fissures from which grow native shrubs and evergreens. This unique method of exhibiting wild animals has proved so satisfactory that similar accommodations have been provided for many other creatures in the zoo.

After visiting the Zoological Gardens one should see the Jefferson Memorial, an imposing marble structure which stands on the site of the main entrance of the World's Fair of 1904. Here one can see relics of the Mound Builders, curios of the Indian tribes who traded with the founders of St. Louis, original manuscripts of the French and Spanish days in Missouri, relics of the pioneers and of the Revolutionary, Mexican, Spanish-American and World Wars. In addition to the third largest collection of Jefferson manuscripts, the Jefferson Memorial holds a large part of the original documents of the Hamilton-Burr controversy, which culminated in the death of one brilliant man and the destruction of the career of another. In the display cases many of the manuscript records of the Lewis and Clark Expedition may be seen.

Of supreme interest today is the complete showing of the famous Lindbergh Collection, including gifts, medals, trophies and souvenirs from a score of foreign countries and from thousands of sources. These have been viewed by more than 5,000,000 persons since they were put on exhibit. From 500 to 1200 people call to see these trophies daily. Colonel Lindbergh recently deeded to the Missouri Historical Society custody of the hundreds of mementos which have come to him in connection with the epoch-making flight of the "Spirit of St. Louis" across the Atlantic, and his friendship tour to the countries of Mexico, Central and South America.

St. Louis' Art Museum, erected during the World's Fair of 1904 as a permanent building, stands on the crest of Art Hill in Forest Park, overlooking the West End residential district and the suburbs which stretch out to the north and west. To its immediate foreground is a vista of sloping landscaped lawn, of glimmering lake and of speeding motor-cars on the winding drives beyond. No other museum building in America has a setting of such natural splendor. This great treasure-house of art is open daily, free to all. Ranked as one of the four best art galleries in the United States, the Museum contains rich exhibits of paintings, casts, sculpture, marble, drawings, architecture and applied art. Many rare canvases, the work of the old masters, are here. Its collection of Chinese bronzes, ceramics and paintings is one of the finest of its kind. Visitors will be especially interested in the period rooms and in the remarkable carved outdoor staircase from Morlaix, in Brittany. St. Louis is one of the few cities in the United States which fosters the development of artistic and cultural facilities for the public by a direct tax for the maintenance and development of its Art Museum, thereby making superior advantages of this kind available to everyone.

During a visit to Forest Park one should not miss a glimpse of the famous Jewel Box, a rare and artistic display of flowers and other plants held regularly in the city's greenhouses located in Forest Park. Thousands of persons annually visit the splendid displays arranged there.

FIG 3 Art Museum

Entirely separate from the Jewel Box is the Missouri Botanical Garden. Founded in 1860 by Henry Shaw, a St. Louis philanthropist, it is popularly known as Shaw's Garden, and ranks second only to the famous Kew Gardens of England. It contains the largest collection of plant life in the western hemisphere and is famous the world over for its wealth of botanical species and its beautiful floral displays. It comprises a city garden of about 75 acres, an out-of-town extension of more than 1,625 acres, and a tropical extension at Balboa, Panama.

At the city garden large conservatories are maintained, containing a varied collection of tropical plants and providing for an almost continuous display of chrysanthemums, orchids, lilies, tropical vines, ferns, palms, Australian, Philippine and Japanese plants, desert cacti and other growing plants. Out of doors are to be found representative gardens of roses, irises, water

lies, and collections of every other kind of plant which can be grown in the region of St. Louis. The orchid and chrysanthemum shows have established national reputations for the gorgeousness and rarity of their blooms and for the beauty and method of their display. Altogether, more than 11,000 species of plants from all climes and all parts of the globe are to be seen here.

FIG. 4 The Jewel Box in Forest Park

One of the best botanical libraries in the country, one of the largest herbaria in the United States, laboratories for scientific work and a school for gardening combine the features of a pleasure-ground with the facilities of an institution of research.

The out-of-town garden, which is constantly being developed, is already one of the best localities in the state for the growing of wild flowers and trees. The propagation of rare and delicate plants away from conditions unfavorable to early plant life incident to a city location is carried on there. Besides growing much material for later exhibit in the city garden, there is gradually being developed an adequate arboretum, which in time will probably become the most complete reservation for trees and native flora in the temperate zone.

MEDICAL ST LOUIS

The St Louis Medical Society was founded in 1836 by a small group of physicians and until 1850 was known as the Medical Society of the State of Missouri. At that time the Missouri State Medical Society was organized, and the name of the local organization was changed to the St Louis Medical Society.

FIG 5 St Louis Medical Society

In the early days the meetings were held in the assembly room of the Public School Library in the Polytechnic Building, then on Seventh and Chestnut Streets, and later a room in the Y M C A was used.

The excellent library of the St Louis Medical Society is an outgrowth of the St Louis Medical Library Association, formerly known as the Medical Exchange Journal Club. The St Louis Medical Society moved into its beautiful new \$400,000 home at 3839 Lindell Boulevard on July 29, 1926. This building was planned and constructed especially for the convenience and comfort of the physicians of St Louis. It contains an auditorium which has a seating capacity of seven hundred, and several private meeting rooms, a dining room and adjoining rooms for entertainment.

On the walls of the first floor lobby there are tablets of Bernard Farrar, the first president of the St Louis Medical Society, William Beaumont, the pioneer American physiologist, who was president of the Society in 1841, and John Thompson Hodgen, well-known St Louis surgeon, who was president of the Society in 1876.

The library occupies the entire second floor and contains more than 30,000 volumes with 325 files of current journals and transactions in

English, French and German. A valuable collection of rare old medical books numbering about 800 volumes, with pictures of medical historical interest, was given to the Society by the late James Monroe Ball and exhibited in one of the rooms on the second floor in connection with the library.

The Bartscher room is a memorial to Dr. Hugo Bartscher from his mother, Mrs. Franciscus Bartscher. It houses many valuable historical collections, rare old medals and books, art exhibits and an excellent display of unusual photography, the work of members. On the walls are several plaques of prominent members donated by their friends in appreciation and commemoration of their valuable service to the Society. The Society has 1,000 active members. Weekly scientific meetings are held in the auditorium. The organization publishes its own weekly bulletin carrying

FIG 6 St. Louis University Medical School

the news of the Society, keeping its members informed as to the programs, local public health statistics, and medical news, including the proceedings of the meetings and scientific papers.

For more than three years the Society has sponsored, edited and broadcast weekly radio talks pertaining to public health matters over one of the local broadcasting stations. During the fifteen-minute program allotted through the courtesy of the station, diseases of common interest are discussed, the name of the editor and speaker being withheld. More than 170 radio talks have been broadcast.

St. Louis University School of Medicine. The School of Medicine of St. Louis University was established in 1837 in a small house on Washington Avenue between Tenth and Eleventh Streets. In 1847 the school was

affiliation between the medical school and the University was severed in 1855, and the medical department became known as the St Louis Medical College and functioned as an independent school

The Marion Sims College of Medicine, founded in 1890 and occupying a building erected for the purpose on Grand Boulevard and Caroline Street, combined in 1901 with the Beaumont Medical College, organized in 1886, and became known as Marion Sims-Beaumont Medical College In 1903 the University assumed control of these schools, which had been merged two years previously, and became known as the St Louis University School

FIG 7 The Firmin Desloge Hospital associated with St Louis University Medical School

of Medicine In the reorganization which ensued the fundamental departments, anatomy, chemistry, physiology, pathology, bacteriology and pharmacology, were placed under the direction of full-time departmental heads

The main building of the original Marion Sims College of Medicine was used until 1927, when the present medical buildings were erected The buildings are located on Compton Hill, one of the highest points in the City of St Louis, the main building facing Grand Boulevard at Caroline Street

An excellent medical library, which has been enriched by several private collections, is housed in the south wing of the building

The University Hospital, affording clinical teaching facilities to the Medical School, embraces a group of three hospitals the Firmin Desloge Hospital, St Mary's Hospital and Mt St Rose Sanitarium. The Sisters of St Mary have placed their educational and medical activities in these institutions under the complete control of the University. By an agreement between the Sisters and the University, the Directors of the various departments of the School of Medicine are made responsible for the corresponding hospital departments, thus forming a compact organization, assuring the

FIG 8 St Luke's Hospital

closest university supervision and the highest type of medical, educational and nursing efficiency

The Alexian Brothers', St Anthony's and St John's Hospitals are known as the "Associated Hospitals." These hospitals afford further teaching facilities and in return are given leadership and guidance in their medical and educational activities. The staffs are appointed by the University.

Intimate association is also maintained among the St Ann's Lying-In Infirmary, St Ann's Founding Society and the St Louis Obstetric Dispensary. These institutions are utilized as teaching centers for obstetrics

and pediatrics Opportunity is also afforded for teaching in the St Louis City Hospital, Isolation Hospital and St Louis City Sanitarium

Washington University School of Medicine St Louis Medical College, founded in 1842, was admitted as a department of the University in 1891 In 1899 the Missouri Medical College, which was founded in 1840, was united with the St Louis Medical College to form the medical school of Washington University This school therefore continues the work of the St Louis Medical College and the Missouri Medical College, two of the oldest medical schools west of the Mississippi River

FIG 9 Jewish Hospital

In 1910, the corporation of the University, appreciating the valuable service which a medical school can render to the community, with the co-operation of the medical faculty, reorganized the school in all departments and appointed heads of departments and instructors in anatomy, physiology, biological chemistry, pathology, medicine, surgery and pediatrics, who devote themselves to teaching and research Associated with this staff are many clinical instructors chosen from the medical profession of St Louis

In 1914 the Washington University School of Medicine moved from its old location on the corner of Eighteenth and Locust Streets to the new buildings facing Forest Park on the corner of Kingshighway Boulevard and Euclid Avenue The buildings of the School of Medicine form a part of a medical group known as the Barnes Hospital group

The affiliation of Barnes Hospital, St Louis Children's Hospital, St

Louis Maternity Hospital, McMillan Eye, Ear, Nose and Throat Hospital, Mallinckrodt Radiological Institute, and Oscar Johnson Institute with Washington University School of Medicine makes these institutions for teaching purposes integral parts of the School of Medicine

FIG 10 Washington University

The Washington University Clinics serve as an out-patient department for the University group of hospitals

Further teaching facilities are afforded by the St Louis City Hospital, including the Isolation Hospital and the City Sanitarium

FIG 11 The Medical Center at Washington University, including Barnes Hospital, St Louis Children's Hospital, St Louis Maternity Hospital, McMillan Hospital, Oscar Johnson Institute and Mallinckrodt Institute of Radiology

FIG 12 St Louis City Hospital

3
An excellent library is housed in the Medical School and several museums and collections for teaching and investigation are maintained by the various departments. Recently a valuable collection of anatomical specimens prepared with unusual skill and care by Bohumil Hochmann has been purchased for the museum. Diseases of bones are well illustrated by a large number of specimens collected during the early history of the school by Dr Charles A. Pope and Dr John T. Hodgen. A section of the museum contains experimental pathological lesions.

The Beaumont Room, adjoining the main reading room of the library, contains manuscripts, letters and other valuable material of the pioneer American physiologist, William Beaumont, presented to the University by his granddaughter, the late Lily Beaumont Irwin. One of the interesting items in this collection is the memorandum book containing Beaumont's original notes of the accident which befell Alexis St. Martin and made possible the renowned investigations in gastric digestion.

Independent Hospitals The hospitals which are directly connected with the two schools of medicine have already been briefly mentioned. There are numerous other excellent hospitals in St. Louis but space does not permit details concerning their many prominent features. Among these independent hospitals are the Barnard Free Skin and Cancer Hospital, Bethesda Hospital, Christian Hospital, DePaul Hospital, Evangelical Deaconess' Home and Hospital, the Frisco Employees' Hospital, Jewish Hospital, Lutheran Hospital, Missouri Baptist Hospital, Missouri Pacific Hospital, St. Ann's Widows' Hospital, St. Louis City Hospital No. 1, St. Louis County Hospital, St. Luke's Hospital, Shriners' Hospital and United States Marine Hospital.

The City of St. Louis, the St. Louis Medical Society, the Medical Colleges of St. Louis and of Washington Universities have through their officers extended to the Fellows of the American College of Physicians a most cordial invitation to hold their 1937 Annual Session in St. Louis. The great hospitals of the City have offered their lecture halls, laboratories and wards for demonstrations and clinics. Members of the local medical profession have signified their willingness and desire to aid in the programs which have been arranged for each morning of the session.

With its two large medical schools and its numerous general and special hospitals, St. Louis offers admirable facilities for the meeting. Indeed, there are so many that it has been found impossible or at least unwise to use all of those which were made available to the committees. Consequently, the greater part of the clinical programs is to be held in only four centers—in St. Luke's Hospital, in the Jewish Hospital, and in the institutions which are associated with the two medical schools. In its teaching, St. Louis University embraces a group of hospitals which includes St. Mary's Hospital, the Mount St. Rose Sanitarium, the Alexian Brothers', St. Anthony's, and St. John's Hospitals, and the beautiful new and modern Firmin Desloge Hospital, where many of the meetings will be held. Washington University is closely affiliated with the Barnes Hospital, St. Louis Children's Hospital, St. Louis Maternity Hospital, McMillan Eye, Ear, Nose and Throat Hospital, the Mallinckrodt Radiologi-

cal Institute, and the Oscar Johnson Institute, the whole forming a medical and health center of outstanding importance. The facilities of the Barnes Hospital will be chiefly used for the meetings.

Many of the scientific discussions and clinics will be contributed by the members of the medical profession of St. Louis. Several distinguished guests, and a few of the outstanding Masters and Fellows of the College from other cities have been asked and have graciously consented to aid in the programs. While there has been scheduled each day a large number of formal programs, it is hoped that the visiting Fellows will find time to view informally the activities in the research laboratories and the points of special interest in the hospitals and medical schools. Among things which should attract particular attention are the Beaumont room of the Library at Washington University School of Medicine, which contains manuscripts, letters and other valuable original material of the pioneer American physiologist, William Beaumont, and the collection of anatomical specimens prepared by Bohumil Hochmann and housed in the museum of the anatomical department at Washington University.

St. Louis also offers to the visitor many attractions other than those of a medical and scientific nature. Among these may be mentioned the world famed Missouri Botanical Gardens, the Art Museum, the St. Louis Zoo, and the Lindbergh Trophies.

It is the sincere hope of the local committees that the St. Louis Session may be memorable among the many enjoyable and profitable meetings of the College.

WHO MAY REGISTER—

- (a) All members of the American College of Physicians in good standing for 1937 (dues, if not paid previously, may be paid at the Registration Bureau)
- (b) All newly elected members
- (c) Members of the St. Louis City Medical Society, without registration fee, upon presentation of their 1937 membership cards
- (d) Medical students pursuing courses at the St. Louis University School of Medicine and the Washington University School of Medicine, without registration fee, upon presentation of matriculation cards, or other evidence of registration at these institutions, exhibits, morning lectures and general sessions
- (e) House officers of the hospitals participating in the program, upon presentation of proper identification exhibits, morning lectures and general sessions
- (f) Members of the Medical Corps of Public Services of the United States and Canada, without registration fee, upon presentation of proper credentials
- (g) Qualified physicians who may wish to attend this Session as visitors. Such physicians shall pay a registration fee of \$12.00, and shall be entitled to one year's subscription to the ANNALS OF INTERNAL MEDICINE (in which the proceedings will be published), included within such fee.

REGISTRATION BUREAU—Temporary Registration Bureau will be open at the Jefferson Hotel on Sunday afternoon and evening, April 18. The permanent Registration Bureau will be located on the mezzanine floor of the Jefferson Hotel. Hours: 8:30 a.m. to 6:00 p.m., daily, April 19 to 23.

REGISTRATION BLANKS FOR ALL CLINICS AND DEMONSTRATIONS, MORNING LECTURES AND ROUND TABLE CONFERENCES will be sent with the formal program to members of the College. Guests will secure registration blanks at the Registration Bureau during the Session.

GENERAL INFORMATION

Headquarters

Jefferson Hotel, 12th and Locust Sts

The Jefferson Hotel will be headquarters for Officers, Regents, Governors and members of the College, also the general headquarters for registration, technical exhibits, general scientific sessions, special lectures and round table conferences

BULLETIN BOARD FOR SPECIAL ANNOUNCEMENTS will be located near the Registration Bureau at the Jefferson Hotel

TRANSPORTATION—On account of recent nation-wide reductions in railroad fares, convention rates are no longer in effect. In a great many instances, however, reduced round trip tickets are in effect from certain localities. Members should consult their local ticket agents.

Special service will be available to physicians from Chicago over the Alton Railroad and from the East (New York City, Philadelphia, Wilmington, Baltimore, Washington, Martinsburg, Parkersburg, and intervening points) over the Baltimore & Ohio Railroad. Special time-tables may be obtained from the Executive Secretary, or by application to local agents of the above railroads.

THE GENERAL BUSINESS MEETING OF THE COLLEGE will be held at 5 05 p m, Thursday, April 22, immediately following the general scientific program of the afternoon. All Masters and Fellows of the College are urged to be present.

There will be the election of Officers, Regents and Governors, the reports of the Treasurer and of the Executive Secretary, and the induction to office of the new President, Dr James H Means, Boston, Mass.

BOARD AND COMMITTEE MEETINGS—The following meetings are scheduled as indicated. Special meetings will be announced and posted.

A *special dinner* will be tendered to the *Board of Governors* by members of the Board of Regents at the Jefferson Hotel, Sunday evening, April 18. An announcement of the time and place will be made later. Members of the Board of Governors are cordially invited.

Friday, April 23, 12 00 m *

BOARD OF GOVERNORS

Room 4, Second Floor, Jefferson Hotel

Monday, April 19, 5 00 p m

Wednesday, April 21, 12 00 m *

* Buffet luncheon served

SPECIAL FEATURES

MONDAY, APRIL 19, 1937

THE ANNUAL SMOKER will be given immediately following the scientific program about 10 20 o'clock in the evening in the Gold Room of the Jefferson Hotel. An interesting and amusing program has been arranged.

WEDNESDAY, APRIL 21, 1937

CONVOCATION OF THE COLLEGE—8 15 p m, Gold Room, Jefferson Hotel. All Masters and Fellows of the College and those to be received in Fellowship.

should be present Newly elected Fellows who have not yet been received in Fellowship are requested to assemble in Rooms 8 and 9, second floor (next floor above mezzanine), of the Jefferson Hotel at 7 30 o'clock, preparatory to the formation of the procession They will occupy especially reserved seats in the central section of the Ballroom, to which they will be conducted by the Convocation marshal promptly at 8 15 As this is the most formal meeting of the College, it is suggested that all appear in evening dress

The Convocation is open to all physicians and their families generally A cordial invitation is also issued to such of the general public as may be interested

Following the Convocation Ceremony, the President will present the John Phillips Memorial Medal for 1936-37 Thereafter will follow the Convocational Oration, "The Organism As a Unity," by Dr John Dewey, Professor Emeritus of Philosophy, Columbia University, New York City

The Presidential Reception will follow immediately after the program Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the Reception

TRUDEAU CLUB LUNCHEON—The Trudeau Club of St Louis cordially invites members of the College who are especially interested in diseases of the chest to attend a luncheon at the Park Plaza Hotel at 12 30 p m on Wednesday, April 21 This will be combined with a round table discussion to be conducted by Dr James Alex Milner Because of the size of the dining room, attendance must be limited to 100 Those desiring to attend should obtain the special Round Table ticket, IV, by advance application or at the Registration Desk before Tuesday noon

THURSDAY, APRIL 22, 1937

THE ANNUAL BANQUET OF THE COLLEGE will be held in the Gold Room of the Jefferson Hotel at eight o'clock All members of the College, physicians of St Louis, and visitors attending the Session with their families are cordially invited Dr Alfred Stengel will act as Toastmaster and Dr Logan Clendening will deliver an address on "Medical Shrines" Following the banquet will occur the annual dance, to which all are invited to stay

PROGRAM OF ENTERTAINMENT FOR VISITING WOMEN

The headquarters of the visiting women will be in the Ladies Lounge on the mezzanine floor of the Jefferson Hotel A program of special features has been arranged, but ample time has been allowed for sightseeing, shopping and recreation Lists including the names of principal shops and restaurants will be issued by the local committee

MONDAY, APRIL 19, 1937

Morning Registration

Afternoon 1 30 p m A personally conducted sightseeing tour to points of interest in St Louis, to Old Cathedral, Shaw's Gardens, Lindbergh Trophies, and to the St Louis Art Museum, where Tea will be served

TUESDAY, APRIL 20, 1937

Afternoon 3 00 p m Fashion Show and Tea at the Junior League Club Cars leave Jefferson Hotel at 2 30

Evening 8 00 p m Bridge, Jefferson Hotel

WEDNESDAY, APRIL 21, 1937

Afternoon 1 00 p m Luncheon and Bridge at the St Louis Country Club Cars
leave Jefferson Hotel at 12 15
Evening 8 00 p m Convocation of the College in the Gold Room at the Jefferson
Hotel All ladies are cordially invited to attend

THURSDAY, APRIL 22, 1937

Afternoon 4 00 p m Tea given by the Woman's Club of the St Louis University
School of Medicine at the residence of Mrs Cyrus Burford
Evening 8 00 p m The Annual Banquet of the College
10 00 p m Dancing
Gold Room, Jefferson Hotel

THE EXPOSITION AND TECHNICAL EXHIBIT will be located on the mezzanine floor of the Jefferson Hotel

The exhibit will be particularly representative of the interests of Internal Medicine, and will include medical literature and texts, pharmaceutical products, apparatus and appliances, specialized physicians' furniture and many other items of special interest These exhibits will afford an opportunity for physicians to keep informed of the latest literature and the newest products in the field of medicine generally, the educational value of these exhibits should never be overlooked Furthermore, exhibitors contribute much not only to the interest of the meeting, but to the financial support of these scientific assemblies Many exhibitors have nothing to sell, but merely seek an opportunity to show what their organizations are attempting to furnish for medical science Every doctor is urged to visit each of the booths, for he will certainly find something new, interesting and scientifically valuable Special intermissions in the general program have been arranged, providing additional time for the inspection of exhibits

GENERAL SESSIONS

Ballroom, Jefferson Hotel, St Louis, Mo

In addition to the program for the General Sessions, attention is called to the Morning Lectures and to the Round Table Discussions The programs for these two

OUTLINE OF SESSION

TIME	MONDAY April 19		TUESDAY April 20		WEDNESDAY April 21		THURSDAY April 22		FRIDAY April 23	
9 00 a m to 12 00 m	Morning free Registration, Exhibits, etc		1st Clinical Session	Morning Lectures (9 30-11 30)	2d Clinical Session	Morning Lectures (9 30-11 30)	3d Clinical Session	Morning Lectures (9 30-11 30)	4th Clinical Session	Morning Lectures (9 30-11 30)
12 00 m to 1 00 p m			Round Table Conferences		*Round Table Conferences		Round Table Conferences			
1 00 p m to 2 00 p m	Luncheon		Luncheon		Luncheon		Luncheon		Luncheon	
2 00 p m to 5 30 p m	1st General Session		3d General Session		5th General Session		6th General Session Annual Business Meeting		7th General Session	
5 30 p m to 8 00 p m	Dinner		Dinner		Dinner					
8 00 p m to 11 00 p m	2d General Session followed by Smoker		4th General Session		Convocation, followed by President's Reception		ANNUAL BANQUET and Dance			

Morning Lectures, Round Table Conferences and General Sessions will be held at Jefferson Hotel, except * Park Plaza Hotel, beginning at 12 15, Round Table 4

features are arranged to supplement the presentations given in the General Sessions. A few of the programs are arranged in the form of symposia while in others no attempt has been made to follow this plan. Some subjects have been discussed intensively—these include

Diabetes and the use of *Long-Acting Insulins*, *Endocrine Disturbances*, *Cardio-vascular Diseases*, with especial reference to *Arterial Hypertension*

Infectious Diseases are given a prominent place with the newer methods of treatment of *Streptococcal Infections*

In addition the program offers presentations on

Medical History, *Neurology*, *Gastro-enterology*, *Diseases of the Bone Marrow*, *Hodgkin's Disease* and *Hypertrophic Arthritis*. *Nutritional Disturbances* as they affect the *heart* and *thyroid* are considered

Syphilis is discussed from its *Public Health Aspect* and A Round Table discussion on its *Treatment* is provided

Thyroid Disease in the negro is discussed and there are miscellaneous papers concerned especially with *Medical Treatment*

The *Convocational Oration* will be delivered by Dr. John Dewey, Emeritus Professor of Philosophy at Columbia University. Dr. Dewey is America's foremost philosopher. He has best understood how the problems of modern life should be stated. His philosophy is a philosophy for daily use and is congenial to those attitudes that are taken instinctively by students of biology and physiology. His subject, "The Organism as a Unity," touches a point of acute interest today, the question, "What shall be the physician's attitude toward the soul-body problem, how shall there be better understanding between internist and psychiatrist?"

FIRST GENERAL SESSION

Monday afternoon, April 19, 1937

p.m.

2 00 Addresses of Welcome

George R. Throop, Chancellor of Washington University

Rev. Alphonse Schwitalla, S. J., Dean of Faculty of Medicine, St. Louis University

Curtis H. Lohr, President of the St. Louis Medical Society

Joseph F. Bredeck, Commissioner of Health, City of St. Louis

Response to Addresses of Welcome

Ernest B. Bradley, President of the American College of Physicians

2 30 The Nature and Treatment of Heart Failure

George R. Herrmann, Galveston, Tex.

2 55 The Role of the Pituitary in Carbohydrate Metabolism

Carl F. Cori, St. Louis, Mo.

3 15 INTERMISSION

4 00 Thyroid-Pituitary Relationship in Diabetes Insipidus

Thomas P. Findley, Jr., St. Louis, Mo.

4 20 Some Recent Studies on Male Sex Hormones

F. C. Koch, Chicago, Ill.

4 45 Experimental Work with the Female Sex Hormone

E. A. Doisy, St. Louis, Mo.

5 10 ADJOURNMENT

SECOND GENERAL SESSION

Monday evening, April 19, 1937

Presiding OfficerO H Perry Pepper, Philadelphia, Pa

- p m
- 8 00 Daniel Drake
Alfred Stengel, Philadelphia, Pa
- 8 30 The Physician Himself as a Therapeutic Agent
William R Houston, Austin, Tex
- 9 00 Protamine and Other Long-Acting Insulins
Russell M Wilder, Rochester, Minn
- 9 30 The Rôle of Nutritional Deficiency States in Cardiac Decompensation
Soma Weiss and Robert W Wilkins, Boston, Mass
- 10 00 The Importance of Ocular Signs in the Diagnosis of Brain Tumor
Ernest Sachs, St Louis, Mo
- 10 30 ADJOURNMENT

10 30 o'Clock

SMOKER

Ballroom, Jefferson Hotel

An interesting and amusing program has been arranged Admission by
registration badge

THIRD GENERAL SESSION

Tuesday afternoon, April 20, 1937

Presiding OfficerJames H Means, Boston, Mass

- p m
- 2 00 Practical Clinical Uses for Lactic Acid and Its Sodium Salt —
Alexis F Hartmann, St Louis, Mo
- 2 25 Healed Bacterial Endocarditis
Louis Hamman, Baltimore, Md
- 2 45 The Relief of Certain Mental Symptoms by Operation on the Frontal Lobes
with Observations upon Vasomotor and Visceral Manifestations
Walter Freeman and James W Watts, Washington, D C

3 15 INTERMISSION

4 00 The Use of Para Amino Benzene Sulphonamide or Its Derivatives in the
Treatment of Beta Hemolytic Streptococcal Infections
Perrin H Long and Eleanor A Bliss, Baltimore, Md

4 30 Bronchiogenic Carcinoma
Evarts A Graham, St Louis, Mo

5 00 ADJOURNMENT

FOURTH GENERAL SESSION

Tuesday evening, April 20, 1937

Presiding Officer

Egeiton L Crispin, Los Angeles, Calif

p m

8 00 Remarks upon the Classification of Bright's Disease and Arterial Hyper-
tension

Willard J Stone, Pasadena, Calif

8 20 The Hereditary Factor in Essential Hypertension

Edgar A Hines, Jr, Rochester, Minn

8 40 Further Studies in the Genesis and Surgical Treatment of Essential Hyper-
tension

George W Crile, Cleveland, Ohio

9 10 Experimental Hypertension Due to Renal Ischemia

Harry Goldblatt, Cleveland, Ohio

9 40 The Surgical Treatment of Peptic Ulcer

Irvin Abell, Louisville, Ky

10 00 ADJOURNMENT

FIFTH GENERAL SESSION

Wednesday afternoon, April 21, 1937

Presiding Officer

David P Barr, St Louis, Mo

p m

2 00 The Clinical Caprices of Hodgkin's Disease

William S Middleton, Madison, Wis

2 25 Hyperthyroidism in the Negro

William B Porter, Richmond, Va

2 50 The Nutritional Factor in Graves' Disease

James H Means, Boston, Mass

- 3 10 INTERMISSION
 3 55 Recent Knowledge Concerning Influenza
 Richard E. Shope, Princeton, N. J.
 4 25 The Internist and Syphilis Control
 Hugh J. Morgan, Nashville, Tenn.
 4 50 A Study of the Diagnosis and Treatment of Lobar Pneumonia According to
 Types and Specific Serum Therapy
 Julien E. Benjamin and Marion A. Blankenhorn, Cincinnati, Ohio
 5 10 ADJOURNMENT

ANNUAL CONVOCATION

Wednesday evening, April 21, 1937

8 30 o'clock

Ballroom, Jefferson Hotel

All members of the profession and the general public are cordially invited. No special admission tickets will be required.

- 1 Presentation of newly elected Fellows and recital of the Pledge
 William Gerry Morgan, *Secretary-General*, Washington, D. C.
- 2 Conferring of Fellowships, and Address
 Ernest B. Bradley, *President*, Lexington, Ky.
- 3 Presentation of the John Phillips Memorial Medal for 1936-37
- 4 Convocation Oration "The Organism as a Unity"
 John Dewey, Professor Emeritus of Philosophy, Columbia University, New York, N. Y.

President's Reception

The Reception will follow immediately after the program. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the Reception.

SIXTH GENERAL SESSION

Thursday afternoon, April 22, 1937

Presiding Officer

William Gerry Morgan, Washington, D. C.

p m

- 2 00 Bone Marrow Biopsies: A Development of the Diagnostic Procedure
 Edward L. Tuohy, Duluth, Minn.

- 2 20 The Differential Diagnosis and Therapeutic Rationale of Diseases Primarily Involving the Bone Marrow
Charles A Doan, Columbus, Ohio
- 2 45 The Occurrence and Treatment of Arrhythmias in Coronary Artery Thrombosis
Arthur M Master, New York, N Y
- 3 10 Early Clinical Recognition of Disturbances in Heart and Blood Vessel Pathology—As Possible Solution to High Cardiac Mortality Rate
Clarence L Andrews, Atlantic City, N J
- 3 30 INTERMISSION
- 4 15 What is Hypertrophic Arthritis?
Walter Bauer, Boston, Mass
- 4 45 The American Board of Internal Medicine and Certification of Internists
Walter L Bierring, Des Moines, Iowa
- 5 05 ADJOURNMENT

The *Annual Business Meeting* of the College will be held immediately after the last paper. All Masters and Fellows are urged to be present. Important amendments to the Constitution and By-Laws of the College are to be presented for consideration and adoption. Official reports from the Treasurer and Executive Secretary will be read, new Officers, Regents and Governors will be elected, and the President-Elect, Dr James H Means, will be inducted into office.

Thursday evening, 8 00 o'Clock

Ballroom, Jefferson Hotel

THE ANNUAL BANQUET OF THE COLLEGE

(Procure Tickets at the Registration Bureau)

Consult Special Banquet Program

Toastmaster Alfred Stengel, Philadelphia, Pa

Address "Medical Shrines"

Logan Clendenen, Professor of Clinical Medicine, University of Kansas
School of Medicine, Kansas City, Mo

Dancing

SEVENTH GENERAL SESSION

Friday afternoon, April 23, 1937

Presiding Officer

Hugh J Morgan, Nashville, Tenn

p m

2 00 The Dementia Precox Problem
Gustave W Dishong, Omaha, Nebr

- 2 20 The Liver in Thyroid Disease
Elmer C Bartels, Boston, Mass
- 2 50 Epigastric Hernia
Louis A M Krause and David Tenner, Baltimore, Md
- 3 15 INTERMISSION
- 3 35 The Chemical Constitution of Gastric Juice and an Estimate of the Value
of Gastric Secretory Studies in Clinical Medicine
Lay Martin, Baltimore, Md
- 3 55 Electrocardiographic Changes in Dogs Following External Injury
Ray W Kissane, Columbus, Ohio
- 4 15 Ebstein's Disease or Congenital Dislocation of the Tricuspid Valve, Report
of a Case with Intraventricular Conduction Disturbances Studied by
Serial Sections Through the Conduction System
Wallace M Yater, Washington, D C, and Morse J Shapiro, Minneapolis,
Minn
- 4 35 ADJOURNMENT

PROGRAM OF MORNING LECTURES

This course of Morning Lectures is a special feature on the program, arranged at the request of a large number of members. The course is presented as an elective, as a whole or for individual days, in place of hospital clinics. Those attending the lectures may also attend the Round Table Conferences. These lectures will be presented daily, Tuesday to Friday, inclusive, from 9 30 to 11 30 a m in the Ballroom of the Jefferson Hotel.

It is intended that the Morning Lectures shall be highly practical, and that the speakers will present their subjects with the aid of lantern slides, moving pictures and other demonstrations. They will consist of three symposia: Tuberculosis, Infectious Diseases and Diabetes Mellitus, and a mixed program.

The lectures will be open to all members of the College, guests of the College, members of the St Louis Medical Society, Senior students of the medical schools of St Louis and House Officers of participating hospitals. *Admission by regular registration badge*

Tuesday Morning, April 20, 1937

ML 1

JEFFERSON HOTEL

John W Williams, Cambridge, Mass
- 10 30-11 00 Subacute Bacterial Endocarditis Active Cases with Negative Blood
Cultures
Chester S Keefer, Boston, Mass
- 11 00-11 30 The Less Common Varieties of Hypertension
Maurice C Pincoffs, Baltimore, Md

ROUND TABLE CONFERENCES

This series of Round Table Conferences is a new feature on the program of the Annual Session of the College. These Round Tables have been scheduled at a time so as not to conflict with the Morning Lectures or the Hospital Clinics.

A national authority has been selected for each topic. Three Round Tables will be in progress simultaneously, and all will be held in adjoining rooms at the Jefferson Hotel, with the exception of the one on Pulmonary Tuberculosis, which will be held at the Park Plaza Hotel. The groups will necessarily be restricted in attendance.

Special tickets, similar to the Clinic tickets, will be required for each Round Table. When application is made for a Round Table it is strongly urged that the *applicant submit in writing a question or topic which he wishes discussed.* These questions will be given in advance to the Leaders of the Round Tables who will discuss such subjects as seem most in demand.

PROGRAM OF ROUND TABLES

Tuesday, April 20, 1937

JEFFERSON HOTEL

Second Floor, Room 9

(Capacity, 100)

- 12 00 m-1 00 p m I ROUND TABLE on Diabetes Mellitus
 Leader Elliott P Joslin, Clinical Professor of
 Medicine at the Harvard University Medical
 School, Medical Director of the George F Baker
 Clinic, New England Deaconess Hospital, Bos-
 ton, Mass

JEFFERSON HOTEL

Second Floor, Room 8

(Capacity, 80)

- 12 00 m-1 00 p m II ROUND TABLE on the Public Health Aspects of
Syphilis
 Leader Thomas Parran, Surgeon-General, United
 States Public Health Service, President of the
 American Public Health Association, Washing-
 ton, D C

JEFFERSON HOTEL

Second Floor, Room 7

(Capacity, 80)

- 12 00 m-1 00 p m III ROUND TABLE on Cardiovascular Problems
 Leader Samuel A Levine, Assistant Professor of

Medicine, Harvard University Medical School,
Senior Associate in Medicine, Peter Bent Brigh-
ham Hospital, Boston, Mass

Wednesday, April 21, 1937

PARK PLAZA HOTEL

(200 N Kingshighway)
(near Washington University and Barnes Hospital)

(Capacity, 100)

- 12 15 p m - 1 00 p m IV ROUND TABLE on Pulmonary Tuberculosis
Leader James Alex Miller, Professor of Clinical
Medicine, Columbia University College of Phy-
sicians and Surgeons, Visiting Physician and
Physician in Charge of Tuberculosis Division,
Bellevue Hospital, New York, N Y
Followed by luncheon as guests of the Trudeau So-
ciety of St Louis
-

JEFFERSON HOTEL

Second Floor, Room 9

(Capacity, 100)

- 12 00 m - 1 00 p m V ROUND TABLE on Gastro-Enterologic Topics
Leader Walter C Alvarez, Head of Section, Di-
vision of Medicine, The Mayo Clinic, and Pro-
fessor of Medicine in the University of Minne-
sota, Graduate School of Medicine, Rochester,
Minn
-

JEFFERSON HOTEL

Second Floor, Room 8

(Capacity, 80)

- 12 00 m - 1 00 p m VI ROUND TABLE on Amebiasis and Malaria, Diag-
nosis and Treatment
Leader Henry E Meleney, Associate Professor of
Preventive Medicine and Public Health, Vander-
bilt University School of Medicine, Nashville,
Tenn

Thursday, April 22, 1937

JEFFERSON HOTEL

Second Floor, Room 7

(Capacity, 80)

- 12 00 m-1 00 p m VII ROUND TABLE on Allergy
 Leader Robert A Cooke, Assistant Professor of
 Clinical Medicine, Cornell University Medical
 College, Consultant in Medicine, New York Hos-
 pital, Director, Department of Allergy, Roosevelt
 Hospital, New York, N Y

JEFFERSON HOTEL

Second Floor, Room 9

(Capacity, 100)

- 12 00 m-1 00 p m VIII ROUND TABLE on Diseases of the Blood
 Leader O H Perry Pepper, Professor of Medicine,
 University of Pennsylvania School of Medicine
 Philadelphia, Pa

JEFFERSON HOTEL

Second Floor, Room 8

(Capacity, 80)

- 12 00 m-1 00 p m IX ROUND TABLE on the Treatment of Various
Phases of Syphilis
 Leader Udo J. Wile, Professor of Dermatology
 and Syphilology, University of Michigan Medi-
 cal School, Ann Arbor, Mich

Please NOTE that all Round Tables are to be held at the Jefferson Hotel,
 except the Round Table on Tuberculosis, which is to be held at the Park Plaza
 Hotel

SPECIAL CLINICS AND DEMONSTRATIONS

Clinics and demonstrations will be held in the forenoons from 9 30 to 12 00
 daily, Tuesday to Friday, inclusive

Tickets will be required for each and every one of the special clinics, ward
 rounds and demonstrations. The cooperation of every one in securing his clinic
 tickets will assist greatly in distributing the attendance according to the capacity
 of each program. It is self-evident that an exercise arranged for fifteen will lose

its value for all if fifty crowd in Ticket registration is the only effective method of keeping the attendance within the capacities indicated

The clinics and demonstrations will be held in the Barnes Hospital, F. M. Desloge Hospital, Jewish Hospital, St. Luke's Hospital, St. Louis University Medical School and Washington University School of Medicine. The full detail of the program will be made available shortly after the appearance of this issue of the ANNALS. From the preliminary notices it is apparent that a very well organized series of clinical meetings will be offered by each institution. There are to be excellent symposia on allergy, endocrine diseases, peripheral vascular disease, hypertension, diseases of the blood, fever therapy, diabetes, diseases of the lungs, emphysema and numerous other clinics and demonstrations covering a wide range of topics in the infectious diseases, diseases of the digestive tract, of the nervous system, etc. In many of these features the staffs of the institutions concerned have added guest speakers of note from other parts of the country. It is felt that the clinical program of this meeting will meet or surpass the highest standards set in previous sessions of the College.

ANNALS OF INTERNAL MEDICINE

APRIL, 1937

NUMBER 10

THE THYREOACTIVATOR HORMONE, ITS ISOLATION FROM THE ANTERIOR LOBE OF THE BOVINE PITUITARY GLAND AND ITS EFFECTS ON THE THYROID GLAND

By EDUARD UHLENHUTH, *Baltimore, Maryland*

THE results of the work to be summarized here and leading to the conclusion that the anterior pituitary manufactures and excretes a specific thyreoactivator hormone by means of which the hypophysis controls the activity of the thyroid, were reported first, by Uhlenhuth and Schwartzbach, in 1926, at the annual meeting of the American Zoologists in Philadelphia.³ A brief account covering all the essential points of evidence was published by Uhlenhuth and Schwartzbach, in 1927.

The history of investigations pertaining to the subject with which the present article is dealing, has been discussed briefly, yet in its most essential features, in "Endokrinologie, 1935, xv, 329-342", in the latter article as well as in many other articles due credit has been given to those who preceded the author. It is for this reason and because of the limitations of space that the author had to omit all references to the work of other investigators.

As we were guided in our work on the thyreoactivator by previous comparative studies of the structure of the thyroid of amphibians (salamanders) and as these morphological studies had yielded important results concerning the functional significance of certain structures of the thyroid and concerning the biological evaluation of pathological conditions of the human thyroid, these comparative morphological studies will appropriately

* Van Meter Prize Essay, 1936. Read before the American Association for the Study of Goiter, June 9, 1936.

From the University of Maryland Medical School.

The work reported in this essay was conducted under the auspices of the Medical School of the University of Maryland, and with the collaboration of the author's students and associates. Financial aid was received from the "Julius Friedenwald Fund for Medical Research," from the "Weaver Fund" and from the "Hitchcock Fund," all three of the University of Maryland Medical School, from the "Elizabeth Thompson Science Fund" of Harvard University and from a gift received personally by the author through the generosity of Mr. Victor Bloede of Baltimore.

form the introduction to our physiological experiments. In order to emphasize that, although we can submit ample evidence indicating a humoral control of thyroid activity, we nevertheless do not believe that the nervous system has no part in regulating thyroid activity, a report of our recent investigations bearing on the nervous control of the thyroid, is appended.

I A FUNCTIONAL INTERPRETATION OF THYROID STRUCTURE

At the time when we became interested in the study of the thyroid gland, a satisfactory functional interpretation of the thyroid structure was not available, in spite of the splendid work of anatomists, physiologists, and clinical scientists such as R. B. Benslev, David Marine, McCallum, Allen Graham, Louis Wilson and others. In fact there was no agreement as to the structural picture of a highly active, as contrasted to a relatively dormant, thyroid. There was even no general consent as to the significance of the thyroid colloid. Many reports appeared at that time maintaining that a scarcity of colloid indicates a low activity, while some English

FIG 1 Showing two different thyroid types of adult salamanders of two different species (same magnification). (a) Gland of adult marble salamander during spring activity, resembling exophthalmic goiter, note star-shaped follicles and numerous colloid vacuoles. (b) Gland of aquatic Colorado axolotl, resembling colloid goiter, note large roundish follicles and absence of colloid vacuoles. (From Roux's Arch., 1927, CIV, 611, figures 27 and 34.)

surgeons (Williamson and Pearse) contended that the colloid is a waste product which, once deposited, never again leaves the lumen of the follicle.

It appeared to us that many of these important questions could be answered, by studies of the thyroid in a group of animals in which this gland normally presents a wide variety of functional states and structural types. Such a group of animals presented itself to us in the so-called salamanders or tailed amphibians. In these animals thyroids ranging from the structure of a human exophthalmic goiter gland to that of a human colloid goiter are found normally (figure 1). It was soon discovered, moreover, that closely allied species and even varieties of the same species possessed widely differing thyroids which not only represented a fixed and

inherited type characteristic for each variety, but were associated with a biology which could be traced back to the functional level of the particular thyroid type. In addition these animals had been previously found to react promptly, when in an aquatic stage, upon administration of thyroid with transformation (metamorphosis) into a terrestrial stage (Gudernatsch, 1913). In this peculiarity a simple means is afforded to use metamorphosis as a test for thyroid activity. Hence an extensive study of the thyroid of salamanders was undertaken. A detailed account of this work was published in 1927.⁵ The essential results of this work are the following:

(a) *The Colloid Plays an Essential Rôle in the Specific Function of the Thyroid*. It was found that during developmental stages at which the thyroid does not function, colloid is stored in the follicles. At the beginning of a functional period it is suddenly, within 24 hours, released from the follicles, but is stored again when the functional period has passed. In a quantitative study of 40 thyroids the total mass of thyroid tissue, the mass of epithelium and the mass of colloid could be expressed in gram weight.* In the graph of figure 2 are shown the absolute weights of the colloid and of the epithelium. It is noticed that during the inactive period colloid is stored, while during the functional period 50 per cent of the stored colloid is released suddenly, several days later the follicles are refilled and the mass of colloid again increases. The same events are shown in figure 3 in which the amount of colloid is expressed in percentages of the total thyroid mass. Evidently colloid is released precisely at the time of thyroid activity. The release of the stored colloid is an essential feature of thyroid activity, the colloid is essential in the specific function of the thyroid gland.^{1, 2}

(b) *Structural Characters of Active and Dormant Thyroid*. Selecting different developmental stages of the thyroid of the same species, and studying, furthermore, the thyroids of different species in which the degree of thyroid activity could be determined by its physiological effects on the biology of the species, we are able to recognize structural characters distinguishing the active from the dormant thyroid.⁵ These are

<i>Active Thyroid</i>	<i>Resting Thyroid</i>
(1) Stainable colloid absent or scarce	Large quantities of stainable colloid
(2) Walls of follicles collapsed, shape of follicles star-like (with papillae and solid cell columns)	Follicles roundish, with regular outlines
(3) Colloid vacuoles numerous	Colloid vacuoles scarce or absent
(4) Cells enlarged and swollen	Cells small and flat
(5) Cells filled with secretion vacuoles (for which we introduced the term "Anderson Vacuoles")	Cytoplasm not vacuolized

In figure 4 are shown the patterns of an active and of a dormant gland of the same species, elucidating points 1 and 2. The difference in the number of colloid vacuoles, existing between an active and an inactive gland is brought out well in figure 1. In figure 5 are illustrated the increase in

* For details of technique see "W. Roux's Arch. f. Entwicklgsmech., 1927, civ, 616."

FIG 3 Showing the functional cycle of the thyroid, colloid expressed in percentages of total thyroid weight, emphasizing the sharp drop in colloid amount during the "Releasing phase," relative to the other thyroid tissues (See Roux's Arch, 1927, civ, 620, table 2)

the cell size and the vacuolization of the cytoplasm so characteristic of the active thyroid

(c) *The "Two-Phase Cycle" of Thyroid Activity* In studying the periods of thyroid activity in one species and correlating them with the corresponding structural appearances it was found that thyroid activity is cyclic and that the entire cycle consists of two phases, a "storage phase" and a "releasing phase" During the former the cells manufacture actively the colloid, excreting it, however, only in one direction, into the lumen of

FIG 4 Showing changes in thyroid pattern during functional cycle of thyroid of same species (a) "Releasing phase," during height of spontaneous (physiological) activity (b) "Storage phase" during dormant period (Redrawn from Roux's Arch, 1927, cix, 611)

FIG 5 Cells of (a) dormant (storage phase) and (b) active (releasing phase) thyroid, at same magnification Note increased cell size and presence of intracellular secretion vacuoles in active gland (Redrawn from figures 72 and 61 in Roux's Arch, 1927, cix, 611)

the follicle where it is stored and eventually leads to a distention (figures 4b and 1b), or even bag-like enlargement of the follicles. During the latter phase the colloid is allowed to escape from the follicles into the blood stream, if the release takes place at a faster rate than the manufacture of colloid, the follicles collapse and assume a star-like shape, the lumina of the follicles changing into mere slits (figure 4a). As the physiological effects of the thyroid hormone are apparent only during the releasing phase of the cycle, the terms "active" or "activated" will be applied henceforth only to thyroids which are in the releasing phase.

(d) *Releasing Factor* On the basis of differential reactions to iodine as observed by Swingle in frogs, and in salamanders in our own laboratory, and guided by the behavior of species in which the thyroid remains permanently in the storage phase, we were led to the conclusion that only the

storage phase is controlled by the thyroid's own, intrinsic powers, while the releasing phase is caused by the effects, upon the thyroid, of an extrinsic agent which we called at that time the "releasing factor" and the nature of which was unknown to us. Our evidence seemed to suggest that the manufacture of colloid and its excretion into the lumen of the follicles are primary and essential functions of the thyroid cells and going on continuously, their rate being dependent only on the degree of distention of the follicles, but that the unique peculiarity of the thyroid, its closed vesicles, has called forth the development of a special extrinsic mechanism controlling the release of the stored secretion from these vesicles.⁵

(e) *Interpretation of Human Thyroid Pathology* A comparison of different types of salamander thyroids with human pathologic thyroids immediately revealed striking resemblances, especially between exophthalmic goiter and the "releasing type" on the one hand, and between colloid goiter and the "storage type" on the other hand. These resemblances were expressed in nine structural and three functional points for exophthalmic goiter, and in eight structural points for colloid goiter. Since it appeared that the two types are merely different stages of one functional cycle and the normal responses of the thyroid to corresponding stimuli, the conclusion seemed unavoidable that in man likewise these two thyroid types could not be considered as the result of a pathological thyroid, but would, on the contrary, indicate the presence of a normal thyroid in the possession of all its normal potentialities and capable of responding normally to the presence or absence of the extrinsic releasing factor. It was suggested that in the case of exophthalmic goiter the disturbance might have to be looked for in the extrinsic releasing factor which in this case appeared to be working overtime ("p. 732").

The evidence in our hands concerning the existence of an extrinsic releasing factor was so convincing that a vigorous search was begun immediately. These studies which were conducted in collaboration with S. S. Schwartzbach, led finally (summer, 1926) and after three years of entirely unsuccessful work with nerve stimulating drugs, to the discovery of the thyreoactivator.

II HUMORAL EXCITATION OF THE THYROID GLAND

Up to 1926 no agent was known by which an artificial stimulation of the thyroid gland could be effected. Our task, as we saw it then, was that of finding a substance by means of which the thyroid could be forced experimentally from the storage phase into the releasing phase, producing thus a thyroid type which would exhibit the essential structural features of this gland at the height of its releasing activity and would therefore resemble the thyroid of a metamorphosing salamander or the human exophthalmic goiter gland.

The results of this work may be summarized under the following points

(a) *The Extraction of the Thyreoactivator (TA)* In our first experiments conducted together with Schwartzbach,^{4,7,8,9,10} three different kinds of bovine pituitary anterior lobe (AL) powder were used. Armour's commercial desiccated AL, and AL powder prepared according to our prescriptions, especially for us by Armour & Co¹, and a powder prepared by ourselves. At present all powders are prepared in our own laboratory by the following method.

The anterior lobes are separated from the posterior lobes by ourselves in the abattoirs,⁷ not later than 40 minutes after the death of the animals. So far only steer pituitaries have been used. Immediately after arrival in the laboratory the glands are cut into small pieces, spread on glass plates and air-dried overnight, by electric fans. If properly manipulated, the glands, neither after this procedure nor at any time later, exhibit any odor of putrefaction. The air-dried material is then desiccated for six days over calcium chloride, ground through a 40 mesh sieve, placed in glass-stoppered bottles and kept, over calcium chloride, in a refrigerator. This powder retains its effectiveness for at least six months.

The powders were extracted, in our first experiments, in acidified Ringer solution (0.5 c.c. of glacial acetic acid per 100 c.c. Ringer) and only occasionally in plain Ringer, the extraction being performed by heating the mixture just to the boiling point. At present plain Ringer is used and the extraction is carried out as follows. A quantity of powder is added to the Ringer solution in such proportions that the final extract will contain TA equivalent to 25 to 200 mg. of dried powder per 0.5 c.c. fluid. The mixture is carefully heated until it almost boils, is filtered immediately, taken up into a syringe and injected as soon as possible.

The appearance of such an extract is that of a clear and markedly pinkish fluid. If the mixture is watched during the process of heating, it is observed that when a temperature close to the boiling point is reached, a loose and flocculent precipitate appears, mingling with the powder particles. On standing the entire mass rises while previous to the formation of this precipitate the AL particles sink to the bottom.

In more recent experiments to be published elsewhere, extracts were prepared by permitting the mixture to stand overnight in a refrigerator and filtering it without heating. Filtration in this instance proceeds very slowly as the fluid is of thick, syrupy consistency. If, after filtration, this fluid is heated, the same loose precipitate observed with the previous technic will form. Extracts prepared by the technic of cold extraction contain thyreoactivator, but we do not know as yet what yield can be obtained by this method. We suspect that it does not result in a separation of the TA from the other hormones contained in the AL.

When extracts prepared by heating are cooled on ice or are permitted to stand for several hours, a fine precipitate falls. Although we have not made specific tests we are under the impression that cooling or standing decreases the strength of the extract.

When the powder is extracted in acidified Ringer, neutralization by N/10 NaOH is necessary. If this is carried beyond a certain point, a precipitate begins to form. Edgar Van Slyke found that the precipitate appears at a pH of 6.8. In experiments conducted together with Norman Wilson we found that extracts precipitated with NaOH and filtered free of the precipitate, have practically lost their power of meta-

* The author takes great pleasure in acknowledging here the valuable assistance and cooperation rendered in this phase of the work by Dr. Frederick Fenger of Armour and Co.

† The author, in behalf of his students and the University of Maryland, wishes to express his gratitude to Mr. Robert Fox, of Greenwald and Company, Baltimore, for the fine spirit of cooperation and generosity which he and his firm have shown to us throughout our work and which in no small measure have made possible our success.

morphosing the larval salamanders, suggesting that the precipitate carries down the TA

Although we have not attempted chemical purification of the extracts, we succeeded, nevertheless, by the simple technic of heating the extracts, in isolating the TA from most of the other AL hormones. The gonads of hundreds of animals were examined, never have we observed gonadotropic effects of our extracts. Together with Frank H. J. Figge²⁰ we have shown that the hypophysis of the animal to be injected may be removed without decreasing, in any degree, the response to the thyroid-stimulating property of the extracts. We are not informed as to a possible adrenotropic component in our extract as the amphibians are not suitable material for such a test. The extract contains, however, some materials which produce, independently of the activity of the thyroid gland, both exophthalmos and a certain degree of tissue dehydration, as observed by Figge and Uhlenhuth²⁰ in thyroidectomized animals injected with the extract.

(b) *Effects of TA on Thyroid Structure* as shown by S. S. Schwartzbach, Guy P. Thompson, and Karl Mech (see references 3, 4, 6, p. 595, 9 and 26)

(1) TA, when injected intraperitoneally, reproduces exactly the structure which had been previously found characteristic of the active (releasing) thyroid.

(2) The colloid is released (see below), the follicles collapse and the lumina become slit-like^{6, 26}

(3) The cells are enormously increased in height and in size generally.

(4) Intracellular secretion vacuoles are present and may replace almost completely the cytoplasm (see references 6, fig. 95, 22, 26).

(5) Colloid vacuoles appear in large numbers.

(6) In addition, more recently it was found that the Golgi apparatus increases greatly in mass at first and later on breaks up into small particles^{17, 22}

(7) And further, that after prolonged injections the unstainable intracellular vacuoles are replaced more and more by deeply staining secretion droplets²²

In figure 6 are shown the more general changes of the thyroid structure as they appear in histological sections. Comparing a normal control (figure 6a) with the thyroid after six TA injections (figure 6b), the swelling and liquefaction of the cells are apparent. After 14 TA injections the almost complete absence of colloid may be seen (figure 6c), and after 22 injections (figure 6d) the presence of numerous droplets in the cells is evident.

In figure 7 is illustrated the vacuolization and liquefaction of the cells as seen in the fresh thyroid of TA injected animals. By the technic of examining the fresh thyroid of the salamander in the moist chamber and with oil immersion, only two days are required to determine whether or not the extract is effective.

FIG 6 Gross histological appearance of thyroid activated by TA (a) Normal control Follicles large, epithelium flat, cytoplasm without secretion vacuoles (b) After 6 TA injections Follicles beginning to collapse, cells greatly enlarged, cytoplasm largely replaced by intracellular secretion vacuoles (c) After 14 TA injections, nearly complete release of colloid (d) After 22 TA injections, cells filled with deeply stained "Colloid droplet"

In figure 8 are shown the cytological changes taking place in the thyroid cells of adult animals after continued TA injections, as seen in microscopical sections In figure 8a are illustrated the cells of a normal, resting thyroid, the cells are filled with very small granules each of them contained within

a vacuole. These granules can be seen in the fresh thyroid and can be stained vitally, in the living animal, with neutral red, for this reason we called them NR-granules. In the fresh gland they move slowly about within

FIG 7 Cells of larval thyroid activated by TA injections as seen in the fresh gland under high magnifications (a) Normal control, neutral red granules numerous, but no secretion vacuoles (b) Activated gland, neutral red granules absent, but many large secretion vacuoles present (c) Activated gland, entire apical region vacuolized (From Uhlenhuth, Schwartzbach and Thompson, *Endokrinologie*, 1935, xvi, 9-19, figure 1)

the vacuole, a movement different from Brownian movement. In addition to the NR-granules, few small deeply staining droplets are present, likewise contained within vacuoles, in most of the dormant glands, however, droplets are absent.

In successful microscopical sections the NR-granules and the vacuoles containing them are of such excellent definition that they show perfectly well in photographs. In figure 9 is shown a follicle from a normal gland, it will be noticed that nearly the entire cell body consists of nothing but these small vacuoles containing each one granule. Owing to this peculiarity the protoplasm appears honeycombed or foamlike, a structure claimed long ago by Butschli as characteristic for all protoplasm.

Figure 8b shows the thyroid after six TA-injections, the cells have now greatly increased in size and the cell plasma is almost completely replaced

FIG 8 Cytology of adult thyroid activated by TA, as seen in histological sections
(a) Normal gland, (b-h) different phases of functional activity of thyroid cells

by large lacunae-like vacuoles. It will be noticed that the NR-granules have disappeared. In figure 8c is seen a thyroid after 15 TA-injections. The vacuoles have disappeared, while the NR-granules have reappeared. At the same time deeply stained colloid droplets have developed. These are of variable size and as they are contained each in a vacuole, the small droplets cannot be distinguished from the large NR-granules. As the number of injections increases, the number and size of intracellular droplets increase (figure 8d). Frequently cells are found now in which the droplets have dissolved into an unstainable fluid deposited in vacuoles (figure 8e). Under physiological conditions the colloid is excreted, by the cells, not in corpuscular form, but as a liquid, by a process of diffusion through the cell walls. Upon excessive stimulation, however, such as is effected by large numbers of TA-injections, colloid passes from the cells into the follicle lumen in corpuscular form, either droplets (figure 8f, partly liquefied droplet) are excreted or the whole apex (figure 8g), or even whole cells are shed. Especially this latter process results in degeneration and disintegration of large

numbers of cells. If TA-injections are discontinued the thyroid, after some time, returns to its normal condition. An arrangement of the granular content of the cell shown in figure 8*h*, with the granules occupying a position close to the nucleus, is a very characteristic stage of this reconstruction period.

FIG 9 Photograph of normal thyroid cells to show vacuoles containing "Neutral red granules"

FIG 10 Showing the increase in size and number of colloid vacuoles (black dots) in the thyroid activated by TA (*b*) as compared to normal thyroid (*a*) (Taken from Figge and Uhlenhuth, *Physiological Zoology*, 1933, vi, 450-465, Plate I, figure d7)

The colloid vacuoles as seen after certain fixatives (Zenker) are illustrated in figure 10, in the gland activated by TA they are greatly increased in numbers as well as in size. The changes in the Golgi apparatus, effected by TA-injections will be evident from an inspection of figure 11

FIG 11 Showing the increase in size of Golgi apparatus in the cells of thyroid activated by TA (b and c) as compared to dormant thyroid (a) (From Quart Jr Microsc Sci, 1934, lxxvi, 615-646, figures 1, 22, 23)

(c) *Colloid Release as Effected by TA* Exactly as in spontaneous activation of the thyroid (see figures 1 and 2) so in experimental activation induced by TA-injections one of the most conspicuous processes is the release of the colloid from the lumen of the follicles. This effect was first noticed by Schwartzbach and Uhlenhuth in 1926 and was described in 1928⁶. Later on it was confirmed by Karl Mech and Eduard Uhlenhuth who devised

a technic by means of which an accurate measurement of the colloid content of the thyroid was made possible. In the following graphs the changes in the "colloid level" (i.e. amount of colloid expressed in percentages of total thyroid tissue) and in the cell height are indicated. It will be noticed that TA-injections are followed by an increase in the cell height and a decrease in the colloid level.

In figure 12, taken from the work of Thompson, Mech and Schenthal²⁸ is shown the effect of discontinuing the TA-injections. Four injections brought the colloid-level down to 8 per cent. After the fourth injection TA administration was stopped, immediately the colloid level began to rise. It is evident that the low colloid level which is the result of the colloid release

FIG 12 The drop of the black line indicates the colloid release effected by four TA injections. The rise of this line indicates that the follicles begin to refill as soon as TA-administration is discontinued. The dotted line indicates that the cell height is effected the reverse way. Note the striking agreement between the experimentally activated and the spontaneously activated (figures 2 and 3) thyroids (Karl F. Mech, Joseph E. Schenthal and E. Uhlenhuth).

effected previously by TA-injections, cannot be maintained after TA is discontinued. What happens when TA-injections are continued over a longer period is shown in figure 13 (taken from the work of J. Schenthal). At first the colloid level drops rapidly until after the sixth injection it reaches as low a value as can be obtained with the dose employed (50 mg AL per injection). After this value has been reached, continued injections maintain the colloid level permanently (over a period of three weeks) at this

FIG 13 *Prolonged TA-injections in adult salamanders* The low colloid level is maintained and the increased cell height persists. Notice that (in the lowest of the three curves) the absolute weight of the colloid runs very nearly parallel to the colloid percentage, the decrease of colloid is so great and persistent, that even the individual variations in size of thyroids cannot mask it. (Joseph E. Schenck and E. Uhlenhuth)

value, but never permit it to rise to the value of the resting gland. Briefly, in our experiments, TA did not lose its efficacy of keeping the colloid level much below its normal value (i.e., at about 25 per cent of the normal colloid level). It will be noticed that the same relation holds true for the cell height which is maintained high throughout the experiment.

From this fact we concluded that at least in respect to colloid level and cell height, we have not felt the need of assuming the action of an "anti-thyreotropic hormone," reported by Collip in his work on warm-blooded animals.

(d) *Bodily Changes Resulting from TA-Injections* (1) We have already mentioned that in the larval aquatic salamander one of the most conspicuous effects of the thyroid hormone is the speedy transformation into an adult terrestrial animal. The same effect is obtained from TA-injections, owing to the release of the thyroid hormone, caused by TA.

(2) Loss of weight

(3) Severe exophthalmos

(e) *Effect of TA on Metabolism* (1) As thyroid hormone raises the metabolism, it was to be expected that TA, because of the release of colloid

FIG 14 Thyreoactivator produces a 200 per cent rise in O_2 -consumption of the normal adult salamander (James U Thompson and E Uhlenhuth)

effected by it, would likewise raise the metabolism. Schwartzbach and Uhlenhuth^{11, 22, 27} found that in larval salamanders the basal metabolism rises from 30 to 115 per cent above the normal, if TA is injected.

(2) In the adult salamander, Thompson ^{4, 20} has shown, in an extensive series of experiments, that oxygen consumption increases up to 200 per cent above normal basal value, if daily injections of TA (equivalent to 50 mg AL) are made (figure 14). It will be observed from the graph in figure 14, that very much as in Collip's experiments on warm-blooded animals, a peak of oxygen consumption is reached after the sixth injection after which metabolism drops, a condition which has been explained by assuming the gradual development of an antithyretotropic hormone in an animal injected with TA over long periods. In the cold-blooded animal such an assumption is not necessary as the drop in oxygen consumption coincides with the time at which all the stored colloid which can be released at all with a given dose of TA, has been released. It is obvious that after this time the amount of colloid excreted into the blood circulation will be, at least, much smaller than the amount of colloid available before this time as the only colloid available from now on will be the colloid manufactured directly by the cells.

FIG 15 Injections of acid Ringer solution (b) and acid extract of posterior pituitary (c) (received 6 intraperitoneal injections of PL extracted from PL powder prepared under the supervision of Dr Frederick Fenger of Armour & Co) do not provoke the appearance of intracellular secretion vacuoles caused by TA-injections (d), no change as compared to normal control (a) (Guy P Thompson and E Uhlenhuth)

(f) *The Power of Activating the Thyroid Is Specific for TA* At first it was uncertain whether the property of activating the thyroid is specific for AL extracts. Large numbers of control experiments were required to test this point ^{3,4,7}. We obtained the following results:

(1) Neither neutral nor acidified Ringer is capable of effecting the changes of the thyroid gland which are obtained by TA-injections (see figures 15a, b, and d, illustrating experiments by Uhlenhuth and Guy P Thompson)

(2) Muscle extract has no effect on the thyroid

(3) Injections of posterior lobe extract are entirely inactive as shown

* The author wishes to express his thanks to Mr O G Harne, of the Department of Physiology of the University of Maryland for his valuable suggestions and assistance in selecting and constructing the apparatus used for the oxygen determinations

by Uhlenhuth and Thompson, figure 15 shows that in the adult animal the structure of the thyroid after posterior lobe injections (figure 15c) is the same as that of a normal control (figure 15a) and entirely unlike that of the thyroid of TA-injected animals (figure 15d). As recently it had been reported that thyroid activation may be obtained by posterior pituitary, Harry A. Teitelbaum tested this substance again in large numbers of animals. Again no activation of the thyroid could be secured by extracts made from bovine posterior pituitary either in alkaline, acid or neutral extractives.

(4) Parathyroid extracts prepared exactly like A.L. extracts did not activate the thyroid, as shown by Schwartzbach and Uhlenhuth (figure 16b).

FIG. 16 (a) Normal control, Ringer-injected, (b) received 4 injections of acid extract of Armour's parathyroid powder, (c) received 3 injections of altogether 1 mg of adrenalin. Neither parathyroid nor adrenalin provokes the formation of secretion vacuoles characteristic of TA effect (Schwartzbach and Uhlenhuth).

(5) Adrenalin, a sympathicotonic substance, was administered to large numbers of animals. Although it produces many of the effects well-known from mammalian work, it does not activate the thyroid. This is illustrated in figure 16, from the work on larval salamanders by Schwartzbach and Uhlenhuth. Further data pertaining to this problem will be reported below.

(6) Pilocarpine, a drug which, among other actions, stimulates the parasympathetic nervous system, does not activate the thyroid gland, as shown in figure 17, from work on larval salamanders by Schwartzbach and Uhlenhuth

FIG 17 Neither immersion into pilocarpine nor pilocarpine injections produce any changes in the normal thyroid gland

(7) Thyroid substance leads to precocious metamorphosis in amphibians and, as in mammals, raises the metabolism of salamanders (shown by James U Thompson, in as yet unpublished work on adult salamanders), but it does not activate the thyroid. On the contrary it leaves the thyroid entirely dormant, as in the more advanced larval stages (figure 18), or even retards thyroid development, as in early larval stages (figure 19)

(8) Iodine affects the thyroid very profoundly, but it has no resemblance, in its action, to TA. At first it leads to pronounced enlargement

FIG 18 Effect of feeding thyroid-substance, upon the thyroid-cells, as demonstrated in the fresh thyroid of the tiger salamander by staining vitally the living animal with neutral red (a) Thyroid cells of normal control larva (b) Thyroid cells of a larva which has been under the influence of iodothyrene for 5 days (c) Thyroid cells of an animal which has been metamorphosed by a 12 days action of iodothyrene. Note that the thyroid cells of the animals treated with thyroid substance have failed to progress toward a more active condition, in particular intracellular vacuoles are absent

FIG 19 Effect of thyroid substance (iodothyrene) on larval salamanders, soon after hatching. It enforced metamorphosis before even the limbs were fully developed, but it did not activate the thyroid, nor speed up its development (a) Normal control early stage of thyroid (b) Thyroid after administration of thyroid-substance. Notice that the follicles are even smaller than in the control, and the cells have not yet attained the same orderly grouping into epithelial walls as they have in the controls

of the follicles and of the thyroid as a whole owing to increased colloid storage, much as it has been found by David Marine in the mammalian thyroid. Later on it brings about destruction of the thyroid cells and finally disintegration of whole follicles, followed by a decrease in the size of the thyroid and eventually by nearly complete disintegration of the organ^{15, 16} (figure 20)

FIG 20 Destructive effects of inorganic iodine on thyroid cells as seen in salamander thyroids taken from animals stained intravitaly with neutral red and examined fresh (a) In the normal gland stainable substance contained in small, evenly distributed granules (b) Advanced lesions after iodine treatment, stainable substance beginning to fuse into lumps (c) Still farther progressed iodine lesions, whole areas in the wall of follicles begin to disintegrate (d) Finally whole follicles are destroyed and disintegrated (Redrawn from Uhlenhuth and Winter, Roux's Arch, 1929, cxix, 516-530)

(9) Thyroid substance produces its physiological effects no matter whether it is injected or fed. Much the same is true, in amphibians, for iodized proteins and amino-acids. Anterior pituitary, however, has no effects whatsoever when it is administered orally. It neither raises the metabolism (Schwartzbach and Uhlenhuth) nor does it change the structure of the thyroid gland (figure 21)

(g) *Physiological Inactivity of TA in the Absence of the Thyroid Gland* (1) After complete removal of the thyroid gland the physiological effects obtainable in normal salamanders by TA-injections cannot be reproduced, as shown by Schwartzbach and Uhlenhuth in 1928¹⁰. It was claimed by Spaul that he could obtain these effects even after thyroidectomy. Figge and Uhlenhuth, in carefully and completely thyroidectomized animals, repeated these experiments,^{19, 20} and confirmed the results obtained previously in collaboration with Schwartzbach.

(2) On the other hand, the presence of the pituitary is not necessary

for the production of these physiological effects after TA-injections. In experiments carried out by Frank H. J. Figge, it was shown that in the complete absence of the anterior, posterior and intermediate lobes of the pituitary, a perfect reproduction of the physiological as well as of the structural effects of TA is possible.²⁰

FIG 21 Oral administration of AL neither has any physiological effects nor does it activate the thyroid gland. Compare thyroid of AL-fed animal (b) with thyroid of normal control (a) (Schwartzbach and Uhlenhuth)

(h) *Conclusions and Confirmations* From all the data reported in this article the following conclusions were drawn (1928)

The anterior lobe of the pituitary manufactures a specific substance, the thyreoactivator, which alone among all the substances tested, is capable of activating, in a specific manner, the thyroid gland. By means of the thyreoactivator hormone, the anterior pituitary controls the activity of the thyroid gland.

The essential results submitted in this article were confirmed soon by other investigators and are now generally accepted. Thyreoactivator has been found to activate the thyroid of fishes (Collip), of amphibians (Houssay and collaborators in 1932), of birds (Schockaert 1930), and of mammals (Loeb and collaborators, 1929, Aaron, 1929, Houssay, in dogs, 1932, Collip, 1934).

III NERVOUS EXCITATION OF THYROID ACTIVITY

Experienced clinical observers, such as Buschan (1896), F. Chvostek (1917) etc., have placed much emphasis on cases of exophthalmic goiter which developed as a result either of continued grave nervous worries or of sudden severe nervous shocks. Owing to the discovery of the humoral

Figure 22

Figure 23

FIG 22 Adrenalin does not activate the salamander thyroid gland, it neither decreases the colloid content of the thyroid nor does it increase the cell height (Mech, Schenthal and Uhlenhuth)

FIG 23 Pilocarpine does not activate the thyroid gland of salamanders, it neither decreases the colloid content nor does it increase the height of the cells of the thyroid (Mech, Schenthal and Uhlenhuth)

excitation of the thyroid gland, interest in the nervous relations of the control of thyroid activity has suffered a setback. It is, however, especially the work of certain noted physiologists, such as Walter B Cannon and Leon Asher, which offers much encouragement to those who would search for some kind of nervous control, in addition to the humoral control of thyroid activity.

The discovery of the thyreoactivator has opened new roads to a successful attack on the question as to whether or not the nervous system plays any rôle in controlling thyroid activity. Our work along this line is based on the idea that, while stimulation of the nervous system may not activate the thyroid, it may make the gland more responsive to the exciting effects of

FIG 24 Adrenalin as well as pilocarpine when injected together with TA, increase the thyroid-activating power of the hormone in salamanders. The colloid content is distinctly more decreased when TA is injected with either adrenalin or pilocarpine than when TA is injected alone (Edgar van Slyke, James U Thompson and E Uhlenhuth)

thyreoactivator. Our results may be summarized under the following points:

(1) Intraperitoneal injections of adrenalin alone do not activate the adult resting thyroid, they neither decrease the colloid level nor do they increase the cell height in the adult resting thyroid (Mech and Schenthal, figure 22)

(2) Intraperitoneal injections of pilocarpine alone do not activate the adult resting thyroid of the salamander, they neither decrease the colloid

Figure 25

Figure 26

FIG 25 In the guinea pig TA combined with adrenalin produces a greater increase in cell height than TA alone, although adrenalin alone has no effect on the cell height of the thyroid (Teitelbaum and Uhlenhuth)

FIG 26 In the guinea pig although pilocarpine alone has no effect on cell height of the thyroid, TA combined with pilocarpine, after the fifth injection, produces a greater increase in cell height than TA alone (Teitelbaum and Uhlenhuth)

level nor do they increase the cell height (Mech and Schenthal, figure 23)

(3) Thyreoactivator injections, when combined either with injection of adrenalin or pilocarpine activates the adult resting gland of salamanders more effectively than thyreoactivator alone does, when either adrenalin or pilocarpine is added to TA the colloid level decreases more (figure 24), and the cell height increases more than when TA alone is injected, as shown by Uhlenhuth and Thompson ²⁴

(4) These experiments were repeated by Harry A. Teitelbaum ³⁰ in guinea pigs. Again it was found that adrenalin (figure 25) or pilocarpine (figure 26) alone has no effect on cell height. But when adrenalin is injected in combination with TA, the cell height is increased more than after TA alone (figure 25). When pilocarpine is injected in combination with TA (figure 26), it has at first a depressing action on TA effect, but from the sixth injection on, it accentuates the TA effect in raising the cell height. This as well as other differences between the amphibian and the mammal cannot be discussed here in detail, suffice it to mention that they are caused chiefly by differences in dosage and reaction to drugs in general.

(5) To test still further the accentuating effects which adrenalin and pilocarpine evidently have upon the power of TA in raising the activity of the thyroid, the amphibian metamorphosis was used as a method of assaying thyroid activity. It was found that in the presence of pilocarpine (dose 2 mg per injection) metamorphosis could be obtained with one-half the number (or less), and in the presence of adrenalin (dose 0.05 mg per injection) with two-thirds (or less) of the number of injections of TA that are necessary to obtain the same effect when TA alone is injected ²³. This result is exactly what would be expected if adrenalin and pilocarpine increase the responsiveness of the thyroid to TA.

(6) Conclusions. While we are not yet in a position to state that the effects we are getting from addition of adrenalin or pilocarpine to TA are caused by the nerve-stimulating properties of these drugs, we have learned that the activation of the thyroid by injections of TA is greatly increased when either adrenalin or pilocarpine is injected in combination with it.

IV SUMMARY AND CONCLUSIONS

(1) The anterior lobe of the pituitary manufactures and excretes a specific hormone, the thyreoactivator, which has the power of activating the thyroid gland (i.e., of causing, among other effects, release of the colloid). By means of this hormone the anterior pituitary is enabled to control thyroid activity.

(2) The effectiveness of the thyreoactivator can be greatly increased when either adrenalin or pilocarpine is injected in combination with it.

AURICULAR FIBRILLATION, THE PRESENT STATUS WITH A REVIEW OF THE LITERATURE

By I C BRILL, M D F A C P, *Portland, Oregon*

AURICULAR fibrillation is a disturbance in the action of the heart, in which the normal contraction of the auricles is replaced by irregular fibrillary twitchings in various parts of the auricular walls. The disorder is believed to arise from a disturbance in the mechanism of the cardiac impulse in which the wave of contraction, instead of following the normal path from the sinoatrial node down the conduction system, pursues a rapid, continuous and irregular course around the mouths of the great veins (circus movement). The resultant fibrillary twitchings, though incapable of causing an effective contraction of the auricles, set in motion innumerable impulses, estimated at four to six hundred per minute, of which only a portion can be transmitted to the ventricles by the conduction system. To this confusion of impulses the ventricles respond with a beat wholly irregular in both time and force and at a rate varying from 100 to 200 per minute (most commonly between 120 and 160), depending upon the integrity of the conducting tissue. Some of the beats are too weak to produce in the peripheral arteries a wave of sufficient magnitude to be perceptible to the palpating finger. The result is a "pulse deficit," the pulse rate at the radial artery being appreciably lower than the heart rate as counted at the apex.

Auricular fibrillation is one of the most important disorders of the cardiac rhythm, and is the commonest type of arrhythmia observed in decompensating hearts. At least 70 per cent of all cases of failure with congestion display this form of arrhythmia (Lewis¹). "Absolute arrhythmia" (*pulsus irregularis absolutus*), "irregular irregularity," and *delirium cordis* are synonyms indicating the essential clinical characteristics of the condition. The term "perpetual arrhythmia" (*pulsus irregularis perpetuus*), formerly used on account of the belief that fibrillation once established was permanent, now has been abandoned, since it is known that many patients frequently suffer repeated attacks which terminate spontaneously (paroxysmal fibrillation).

HISTORY

Although the existence of a condition characterized by an absolutely irregular pulse was known to clinicians for many years, it was not until 1903 that it was first described by Hering² as a distinct clinical entity. In 1906 Cushny and Edmunds³ described a patient with paroxysmal irregularity of the heart and suggested that the irregularity might be the clinical counterpart of auricular fibrillation which they had already observed in their laboratory animals. In 1909 this correlation was definitely established by Rothberger

* Received for publication October 10, 1936

and Winterberg,⁴ and independently by Lewis⁵ In 1910 Fox⁶ and in the same year Mackenzie⁷ reported patients with auricular fibrillation in whom no structural defects of the heart could be detected, and in 1913, from clinical and pathological observations on a young subject (aged 23), Gossage and Hicks⁸ demonstrated fairly conclusively that this condition can occur in a heart which is normal apart from the fibrillation In 1914 Wenckebach⁹ reported the discovery by a patient that auricular fibrillation was favorably influenced by quinine, and in 1918 Frey¹⁰ showed that quinidine, the dextroisomer of quinine, is the more effective therapeutic agent in this condition In 1918-1920 Lewis, Feil, and Stroud,¹¹ and in 1921 Lewis, Drury and Ihescu¹² published their studies which tended to support the concept that the "circus movement" of a contraction wave was the physiological disturbance of the cardiac mechanism in clinical fibrillation This concept was based originally on the observations of earlier writers, especially those of Mines,¹³ Mayer,¹³ Garrey,¹³ and Levy¹³

ETIOLOGY

In the light of available information no definite etiological factor is recognizable in auricular fibrillation It is indeed known that auricular fibrillation is most often associated with certain types of heart disease, namely, rheumatic valvulitis, particularly mitral stenosis, and hypertensive heart disease It is also known that the arrhythmia occurs frequently in hyperthyroid states, with or without other evidence of heart disease However, less frequently auricular fibrillation has been observed in all other types of cardiac disorder, and in many instances where the heart, apart from the fibrillation, was apparently entirely normal It occurs at any age, though it is infrequent under the age of 20 years, and is very rare under the age of twelve The heaviest age incidence is in the third and fourth decades in the valvular group, and in the sixth and seventh decades in the non-valvular group The sex incidence does not appear to be particularly significant It has been found to vary widely in different groups of patients White¹⁴ noted about twice as many males as females showing the arrhythmia, while Cookson¹⁵ found twice as many females as males Evans¹⁶ in a comparatively small group of cases found a slight predominance of females in the rheumatic patients, and a ratio of three males to one female in the non-rheumatic group Brown¹⁷ in an analysis of 119 non-rheumatic cases showing auricular fibrillation which came to autopsy, found males predominated over females in a proportion of two to one However, of the 15 cases in this series which showed no cardiac pathology, 12 were females and three males In Friedlander and Levine's¹⁸ series of 35 cases of fibrillation without evidence of organic heart disease, there were 32 males and only three females

INCIDENCE OF ASSOCIATED HEART DISEASE

Of the various forms of cardiac disorder with which auricular fibrillation is apt to be associated, rheumatic heart disease represents the largest group. Evidence of this form of heart disease is found in more than 50 per cent of all cases of fibrillation. In a recent tabulation of 14 available reports, comprising a total of 2958 patients with auricular fibrillation, Evans¹⁶ found the incidence of rheumatic heart disease to vary from 20 to 69 per cent, or an average of about 49 per cent. In his own group of 39 patients, rheumatic heart disease occurred in 22, or 54 per cent.

Second in importance is the non-valvular or non-rheumatic type of heart disease occurring in relatively elderly people (Cookson¹⁵, Stroud, Laplace and Reisinger¹⁹, Levine²⁰). There is some disagreement as to the exact nature of the pathological process represented by this group. Levine²⁰ described it as "the condition called chronic myocarditis in middle-aged or elderly people in whom there is no important disease of the valves but rather some functional or structural damage to the musculature of the heart." Cookson¹⁵ found in this group "no constant associated conditions, except that of age." On the other hand, Brown¹⁷ in his series of 119 cases of this type found that hypertension was the etiological factor in 79.3 per cent of the cases with permanent fibrillation, and in 86.5 per cent of the cases with transient fibrillation. Both Cookson and Brown found coronary disease insignificant as an etiological factor in this arrhythmia. Parkinson and Campbell²¹ noted hypertension in 24 per cent and "myocardial disease" in 22.5 per cent of 200 cases of paroxysmal fibrillation. It is possible that some of their "myocardial" patients properly belong to the hypertensive group. Fourteen of those patients showed "gross enlargement of the heart or signs of congestive failure," without evidence of arterial disease or any other etiological factor to account for the enlargement or the congestive failure. It was pointed out by Bell and Clawson²² that a diagnosis of primary hypertension is justified "in a person suffering from chronic cardiac disease with low or normal pressure, if there is a demonstrable cardiac hypertrophy of the left ventricular type not associated with any disease known to cause hypertrophy." Yater²³ in a study of 145 cases of auricular fibrillation found hypertension a commonly associated condition in the non-rheumatic group. The weight of evidence, therefore, points to hypertension as the clinicopathologic disturbance most often found in the non-valvular type of heart disease associated with fibrillation. This is not an unexpected finding in view of the known importance of hypertensive disease in the causation of non-valvular heart disorders.

The frequent association of auricular fibrillation with thyrotoxicosis has been noted by many observers and is now quite generally recognized^{24, 25, 26, 27, 28}. In the 2958 cases of auricular fibrillation, which Evans¹⁶ collected from the literature, the occurrence of thyroid disease ranged between 0 and 44 per cent, with an average incidence of about 9 per cent. In the 200 cases

with paroxysmal fibrillation of Parkinson and Campbell,²¹ there were 28 cases or 14 per cent associated with goiter. Obviously the incidence of thyrotoxicosis in this arrhythmia varies with the geographical distribution of goiter.

The nature of the injury suffered by the heart in thyrotoxicosis remains obscure. The majority of opinion holds that no permanent cardiac damage results even though intense hyperthyroidism has existed over a considerable period of time. The whole subject has been comprehensively reviewed in a recent paper by Maher and Sittler.²⁰ In a series of 180 cases of their own these authors found that "congestive heart failure was not present in uncomplicated thyrotoxicosis. The presence of this phenomenon was associated with the coexistence of a structural lesion. Abnormal cardiac physiologic function as determined clinically or demonstrated objectively by the electrocardiogram, such as heart block (all types), damage to the ventricular conduction system and auricular fibrillation, appeared to be manifestations of primary organic heart disease modified by the element of thyrotoxicosis. The effect of thyrotoxicosis appeared to be that of a catalytic agent. The course of the organic heart disease progressed more rapidly when thyrotoxicosis was active. The thyrotoxicosis brought to the surface latent cardiovascular lesions, which resumed their latency on the successful termination of the thyroid toxemia."

The association of auricular fibrillation with syphilitic heart disease is very uncommon. In his own series of 39 cases with persistent fibrillation, Evans¹⁶ found no instance in which syphilis was present. In the 2958 cases collected from the literature, the incidence of syphilis was approximately 1.5 per cent. Parkinson and Campbell,²¹ in their series of 200 cases of paroxysmal fibrillation, found syphilitic aortitis in five instances or 2.5 per cent.

The association of angina pectoris with auricular fibrillation is likewise uncommon. Cookson¹⁵ found only five such cases in a series of 2000 patients with fibrillation. The extraordinary rarity with which angina pectoris is observed in auricular fibrillation tends to support the conclusion of Brown¹⁷ and of Cookson¹⁵ that coronary disease is not a significant etiological factor in this arrhythmia. However, the writer has observed frequently the transient occurrence of fibrillation during the early course of acute coronary thrombosis. This also has been noted by others (Levine³⁰).

The relationship between auricular fibrillation and subacute bacterial endocarditis is remarkable. Both conditions are common complications in rheumatic heart disease, but it is well known that they very rarely occur together. High grade mitral stenosis appears to favor the development of fibrillation, bacterial endocarditis is more apt to be engrafted upon a mildly affected mitral valve and upon a deformed aortic valve (Fulton and Levine³¹). In a series of 1200 cases of auricular fibrillation Cookson¹⁵ noted three instances (0.25 per cent) in which fibrillation and infective endo-

carditis were associated. Two of the patients came under observation with both conditions already present. In the third case fibrillation developed just before death. He could find "no example in the literature in which the infection has developed in a patient already under observation with auricular fibrillation."

THE OCCURRENCE OF AURICULAR FIBRILLATION IN AN OTHERWISE NORMAL HEART

Since the demonstration in 1913 by Gossage and Hicks⁸ that auricular fibrillation may occur in a heart which is entirely normal apart from the fibrillation, there have been numerous confirmations of this observation. In 1926 Levine²⁰ reported "several individuals with transient auricular fibrillation and one with the permanent form who, after the most thorough examination, showed no evidence of any disease whatever, the heart except for the arrhythmia seemed entirely normal."

Parkinson and Campbell²¹ (1930) found no evidence of heart disease in 30 (15 per cent) of 200 cases of paroxysmal fibrillation. In 12 (6 per cent) of these patients there were "infective" and "toxic" conditions that might have caused the arrhythmia, in the remaining 18 (9 per cent) there was no apparent cause.

Fowler and Baldrige³² (1930) reported 10 patients in whom auricular fibrillation was the only evidence of cardiac disease. Seven of these were of the paroxysmal, and three of the persistent variety. In one of these patients the "fibrillation was attributed to the removal of cerumen from the external auditory canal, one to exertion, four to alcohol, one to carbon monoxide, one to ether and nitrous oxide anesthesia, and two were in attendance at gasoline stations." One of the patients who fibrillated for two and one-half years, later came to necropsy and "the heart was regarded as grossly and microscopically normal." These authors also collected 35 similar cases from the literature. In the latter the "fibrillation was attributed to such stimuli as electric shock, diseases within the abdomen, emotion and effort, and intoxication by various chemical substances."

Friedlander and Levine¹⁸ (1934) reported 35 cases of auricular fibrillation without evidence of organic heart disease. Of these, 13 were classified as transient, and 22 as permanent. This number represents approximately 6 per cent of all patients with fibrillation seen by them over a period of 14 years. The inciting factors in this group in order of frequency were exertion, gastrointestinal disturbances, alcohol, and upper respiratory infections. In 20 patients there was no ascribable cause.

Organ, Wolff, and White³³ (1936) reported a similar series of 49 cases of auricular fibrillation without other signs of cardiac disease. This group likewise represents approximately 6 per cent of the total number of patients presenting this arrhythmia seen by them over a period of years. Only three of these cases were classified as permanent, and 46 were of the transient or

paroxysmal type Two of these cases which came to necropsy presented normal cardiac findings In many of the cases there were no definite etiological factors In some the onset of the arrhythmia appeared to "be related to pneumonia, malarial chill, pelvic abscess, alcohol, ether, burns, gall-bladder colic, vomiting, surgical operation, exertion, and emotion" In no instance, however, "when more than one paroxysm had occurred was the same etiologic factor responsible for all or even more than two paroxysms in the same person"

EFFECT OF DRUGS AND CHEMICALS ON THE INDUCTION OF AURICULAR FIBRILLATION

Drugs and chemicals as primary factors causing fibrillation cannot be considered of great importance Organ, Wolff, and White³³ collected from the literature instances in which the occurrence of fibrillation in normal hearts was attributed to epinephrine, digitalis, acetylsalicylic acid, ether, alcohol, tobacco, hydrogen sulphide, arsenic, carbon monoxide, and gasoline fumes These rare occurrences, however, rather than being regarded as illustrations of specific pharmacological action, may be more logically viewed either as isolated instances of drug idiosyncrasy, or as examples of the "trigger" mechanism suggested by Friedlander and Levine¹⁸ According to this concept the drug or chemical acts as a trigger upon a heart which, though structurally normal, is yet functionally so altered as to be subject to the sudden inception of auricular fibrillation upon coming in contact with some irritating or exciting agent The same mechanism is suggested by these authors as a possible explanation of the spontaneous occurrence of fibrillation in certain otherwise normal individuals In such cases "it is possible that an inherent susceptibility to functional nervous instability provides a fertile field for the propagation and persistence of aberrant stimuli whenever these people are subjected to a particular inciting factor, i e, emotional strain, acute febrile or toxic disorders the trigger may be related to the adrenal gland"

As secondary factors in initiating fibrillation in definite disease states, the rôle of certain drugs and chemicals appears more clearly established McEachern and Baker³⁴ have induced fibrillation by the administration of digitalis in nine patients with cardiovascular syphilis This is particularly significant in view of the rarity with which fibrillation is ordinarily observed in syphilitic heart disease Recently Tung³⁵ reported the appearance of transient auricular fibrillation in 15 patients in association with full or excessive digitalization, and the disappearance of the arrhythmia on the withdrawal of the drug Twelve of these patients presented gross evidence of heart disease Of the remaining three, one suffered from mitral valvular obstruction due to a myxoma of the left atrium, and in another there was severe toxemia from suppurative pneumococcal pleurisy The third pa-

tient was an elderly man (64 years of age) with a carcinoma of the esophagus, atelectasis of the left lung, and displacement of the heart to the left

Rosenblum, Hahn, and Levine³⁶ produced transient auricular fibrillation in hyperthyroid animals by the injection of doses of epinephrine too small to alter the cardiac rhythm of normal animals or those with hypothyroidism Nahum and Hoff³⁷ have converted a normal heart mechanism into auricular fibrillation by the administration of 0.75 mg of acetyl-B-methylcholine chloride per kilogram of body weight in four patients with hyperthyroidism, but were unable to induce such changes in normal persons with even larger doses of the drug They were also able to produce fibrillation by means of the drug in electrically shocked animals Since the principal action of acetyl-B-methylcholine chloride is vagus stimulation, these investigators conclude that the production of fibrillation in the above described instances was the effect of two distinct factors (1) a vagus factor (from the action of the drug), and (2) an exciting agent acting on the heart (thyroxine or electric shock), which they designate as the "E factor" In consideration of the above described observations Nahum and Hoff³⁷ seek to explain the mechanism of clinical fibrillation as involving the interplay of the same two factors The "E factor" is represented by the stretching of the auricular musculature as in mitral stenosis and in congestive failure, by the overactivity of the thyroid in thyrotoxicosis, and by functional nervous instability in some organically normal hearts In the presence of any of the above-named states ("E factors"), should overactivity of the vagus develop, or should the individual be abnormally vagosensitive, auricular fibrillation may result This theory is not incompatible with the "trigger" concept of Friedlander and Levine

From the above considerations it appears clear that no well defined factor is recognizable as the cause of auricular fibrillation It seems rather that the development of the arrhythmia is dependent upon the interplay of a number of circumstances which most often arise in the presence of grave heart disease especially in mitral stenosis and hypertension, and in certain toxic states particularly thyrotoxicosis These circumstances, however, may also arise in apparently healthy states and initiate the arrhythmia in individuals with otherwise normal hearts The latter group constitutes probably about 4 to 9 per cent of all cases of auricular fibrillation

PATHOLOGY

Yater²³ studied microscopically 29 hearts which had been the seat of fibrillation From these observations and from a comprehensive review of the literature, he came to the conclusion that there were no specific histologic lesions characteristic of this arrhythmia This is in agreement with the previously published observations of Frothingham,³⁸ and similar conclusions have been reached by Cookson,¹⁵ Lewis,¹ White,¹⁴ Brown,¹⁷ Stroud, Laplace and Reisinger,¹⁹ and Friedlander and Levine¹⁸ Indeed, this now appears to be the generally accepted view

TYPES AND FREQUENCY OF FIBRILLATION

Fibrillation is classified as (1) persistent, permanent, or established, and (2) as transient or paroxysmal. Both varieties may occur in any type of heart disease or in a heart which is otherwise normal. Furthermore, the transient variety may, after a number of paroxysms, become permanently established. However, mitral stenosis more often favors the establishment of persistent fibrillation, while the transient type is more often associated with the non-rheumatic group and with the otherwise normal heart. Comparatively few statistics which bear on the relative frequency of the two types are available. In White and Jones' ³⁹ series of 376 cases of fibrillation which included 30 patients without other evidence of heart disease, 309 (82.2 per cent) were classified as established, and 67 (17.8 per cent) as paroxysmal. In Kohn and Levine's ⁴⁰ group of 49 cases, including three cases in which no other heart disease was demonstrable, 46 were classified as permanent fibrillation, and three as transient. (It is not indicated whether the three transient cases were among those with structural heart changes or coincided with the three patients in whom no other evidence of heart disease was demonstrable.) In three small groups of cases including only patients with no other evidence of heart disease the relative frequency of the two types was

	Permanent	Paroxysmal	Total
Oigam, Wolff and White ³³	3	46	49
Friedlander and Levine ¹⁸	22	13	35
Fowler and Baldridge ³²	3	7	10

DURATION OF THE PAROXYSMS

In the series of 200 patients observed by Parkinson and Campbell, ²¹ 160 had paroxysms lasting less than two days. In these the duration of the paroxysms varied from one to 48 hours. In 20 cases the attacks lasted from two to four days, and in eight the paroxysms varied in duration between four and seven days. The remaining 12 patients had paroxysms lasting longer than seven days, some of these attacks continued as long as three weeks.

Oigam, Wolff and White, ³³ in their series of 49 patients, noted "great variation in the duration of paroxysms—from the shortest of a few minutes to the longest lasting one year." Usually, however, the paroxysm lasted "a few hours or days."

Friedlander and Levine ¹⁸ "arbitrarily" classified the arrhythmia as permanent if it lasted longer than seven days, because "it was assumed that any attack lasting more than a week would not be likely to cease spontaneously."

The above observations appear to justify the conclusion that in the large majority of cases of transient fibrillation (over 90 per cent) the paroxysms do not last longer than seven days, but that in very rare instances a paroxysm may continue for as long as one year and may then cease spontaneously.

SYMPTOMATOLOGY

Palpitation is the most common symptom. There may also be exhaustion, breathlessness, faintness, and giddiness. Pain is rarely a complaint. Orthopnea was the first symptom complained of by one patient observed by the author.⁴¹ The onset of the attack may not be accompanied by any particular disturbance, so that the patient may not be aware that the cardiac rhythm has changed. In rare instances the onset is very stormy, being accompanied by intense distress with symptoms of shock, and prostration. In most cases, however, the patients become aware of the sudden onset of palpitation and experience a varying amount of discomfort without complete disability.

DIAGNOSIS

The diagnosis rarely offers any appreciable difficulty. In most cases the existence of the arrhythmia can be diagnosed by means of the palpating finger and stethoscope or naked ear. Levine,²⁰ quoting Sir Thomas Lewis, gives the following rule: "Given a decompensated cardiac with a heart rate as counted at the apex of over a hundred and a radial pulse that is appreciably less (a pulse deficit of ten or more beats) if the rhythm seems grossly irregular and the pulse is irregular in both time and force the condition is auricular fibrillation nine times out of ten."

The arrhythmia resulting from very frequent, irregularly spaced extrasystoles occasionally constitutes a problem in differential diagnosis. In that condition, as in auricular fibrillation, short, quick beats are followed by compensatory long pauses. However, in fibrillation long pauses also occur frequently after strong beats, a phenomenon not seen in the extrasystolic arrhythmia. Any factor which accelerates the pulse rate (e.g. exercise or atropine) tends to increase the arrhythmia of fibrillation, and diminish the irregularity due to ectopic beats. Conversely, any agent which lowers the pulse rate tends to diminish the irregularity of fibrillation and to accentuate the arrhythmia resulting from extrasystoles. Finally, the diagnosis can be established beyond the possibility of a doubt by means of graphic methods. The disappearance of the auricular wave in the polygraphic tracings confirms the absence of auricular systole. In the electrocardiogram this condition is indicated either by a complete absence of P-waves, or by a succession of rapid, irregular, fundamental oscillations upon which, in turn, still more quivers are superimposed. The ventricular complexes are very irregularly spaced, but are otherwise normal in design except for such changes as may be due to associated disease involving either ventricle.

THE EFFECT OF AURICULAR FIBRILLATION ON CARDIAC FUNCTION

The effect of fibrillation on cardiac function varies greatly. In some instances, at least for a considerable time, little or no harm appears to result from the arrhythmia, especially if the heart action is maintained at a rea-

sonably slow rate, either by digitalis or by organic heart block without drugs (White¹⁴) Friedlander and Levine¹⁸ observed a patient who had never received medication and was known to have had persistent auricular fibrillation for 31 years without incapacitating him until five years prior to his death when he developed a left homonymous hemianopsia undoubtedly due to cerebral embolism Another of their patients "has remained well for years without medication although the rate is always rapid"

In other instances, grave disturbance in cardiac function may follow rapidly the onset of fibrillation, even if no structural changes of the heart can be demonstrated by all available clinical means Such a case was recently observed by the author⁴¹ A married woman, aged 43 years, with an excellent past history began to fibrillate without apparent cause After fibrillating for about three months without treatment she developed severe congestive failure There was generalized edema with signs of fluid in the serous cavities Rest and digitalization for one week reduced the heart rate from 160 to 85, produced extensive diuresis with a loss of 15 pounds in weight, and restored compensation to a considerable extent Roentgen-ray examination disclosed that the pleural and pericardial effusions had largely disappeared and the cardiac shadow was nearly normal The electrocardiogram showed that the auricles were still fibrillating but that the heart was otherwise normal except for slight changes due to digitalis A "test" dose of 3 grains (0.2 gram) of quinidine was administered When the patient was examined two hours later the heart rhythm was found to be normal Quinidine in half grain doses twice daily was continued for two days Thereafter all medication was stopped Within one month the patient resumed her normal mode of life At this writing, 15 months since the last dose of quinidine, the patient remains entirely well As nearly as can be determined by all the clinical means available, including roentgen-rays and electrocardiographic studies, her heart is entirely normal

The only example found in the literature resembling this significant history is that of Case 186 reported by Parkinson and Campbell²¹ These authors point out "how much disability may be produced by fibrillation, apart from any other diseases of the heart"

Between the two extremes just described are found the larger number of patients in whom the arrhythmia causes a degree of cardiac embarrassment which adds measurably to the distress already present in the organic cases, and produces a certain amount of breathlessness and palpitation in those persons whose hearts are otherwise normal On the other hand, as already pointed out, and for reasons not altogether clear, the presence of auricular fibrillation very greatly reduces the possibility of the development of subacute bacterial endocarditis, and to a considerable extent lessens the severity of the pain of angina pectoris (Cookson¹⁵)

It is generally accepted that auricular fibrillation predisposes to the formation of auricular thrombi (Kohn and Levine⁴⁰), but that notwithstanding this increased tendency to thrombus formation, embolism is no more com-

mon than when the rhythm is normal (Lewis,⁴² Cookson,¹⁵ Kohn and Levine⁴⁰) However, embolism does occur more frequently when after prolonged fibrillation the rhythm changes to normal Apparently the sudden onset of normal rhythm is an important factor in the production of emboli (Mackenzie,⁴³ Kohn and Levine⁴⁰)

PROGNOSIS

In patients with fibrillation without other evidence of heart disease the outlook is very favorable In their group of 49 cases, Organ, Wolff and White³³ found few cardiovascular changes, "rarely serious and in some instances wholly incidental to the presence of fibrillation Hyperthyroidism was an uncommon complication The mortality from auricular fibrillation or from cardiac disease was almost negligible" These conclusions are in agreement with those of Parkinson and Campbell²¹ and of Friedlander and Levine¹⁸ In striking contrast is the unfavorable prognosis held by fibrillators with organic heart disease The average duration of life in such groups observed by Stroud, Laplace and Reisinger¹⁹ and by Cookson¹⁵ was from two and one-half to seven years The shortest duration of life was noted in those patients with organic heart disease who began to fibrillate before they reached the age of 20 years Their average length of life after the onset of fibrillation was less than one year A comparison of the prognosis in the two chief etiological groups, the rheumatic and the non-rheumatic, revealed no significant difference (Stroud, Laplace and Reisinger¹⁹)

TREATMENT

In a recent paper on this subject Kohn and Levine⁴⁰ state "It is indeed questionable whether any form of therapy to restore the normal rhythm is indicated in this condition" This statement must be construed strictly as being applicable only to fibrillation associated with grave organic heart disease, especially rheumatic mitral stenosis, for it is in this type of case that the dangerous untoward effects of quinidine (embolism, collapse, and sudden death) are most apt to manifest themselves It may be stated, therefore, that in advanced organic heart disease with auricular fibrillation of long standing the best results are usually obtained by adequate digitalization, sufficient to maintain a reasonably slow rate (70 to 80 per minute) and to reduce the pulse deficit to a minimum In such instances it is probably undesirable to attempt to abolish the arrhythmia by means of quinidine, for the normal rhythm thus established is not likely to be permanent and the benefits derived therefrom are not sufficient to compensate for the risk involved in the use of the drug On the contrary, occasional cases of organic heart disease with congestive failure appear to derive some advantage from auricular fibrillation since the heart rate may be slowed to more efficient levels with digitalis and the response to that drug is often better than when the rhythm is normal It also has already been pointed out that auricular

fibrillation reduces very greatly the possibility of the development of sub-acute bacterial endocarditis and sometimes lessens the severity of the pain in angina pectoris

Notwithstanding these apparent advantages of auricular fibrillation there are many obvious disadvantages in the continuation of the abnormal rhythm. Perhaps the most important of these is the relationship of the arrhythmia to embolic accidents, for although, as noted above, it is held by some authorities (Lewis,⁴² Cookson¹⁵) that, except under quinidine therapy embolism is no more common in cases with auricular fibrillation than in similar cases with normal rhythm, it is generally accepted that this arrhythmia predisposes to the formation of auricular thrombi. It is also fair to assume that if the auricular fibrillation is terminated shortly after its inception the chances for the formation of such thrombi are greatly reduced. The conclusion therefore seems justified that whenever possible without too great risk, the attempt should be made to establish normal rhythm. In auricular fibrillation of short duration (less than six months) occurring in cases where the organic heart changes are not too far advanced, the dangers attending the use of quinidine are relatively less serious. Hence, in such cases quinidine preceded by digitalization may be used with probable benefit and comparative safety.

The use of quinidine is also worthy of trial in the more advanced cases of chronic heart disease with severe decompensation which fail to respond to digitalis or any other form of treatment. Cases of this type have been reported (Van Nuys⁴⁰, Kohn and Levine⁴⁰) in which quinidine used as a last resort established normal rhythm and restored compensation.

In cases of auricular fibrillation without other evidence of heart disease, quinidine is the most effective therapeutic agent and is the therapy of choice. In such cases dangerous toxic effects from the drug are seldom encountered and the chances of success are further increased by preliminary digitalization (Sollman⁴⁷). After such preparation, a test dose of 0.2 gram of quinidine is administered. In some instances this single "test" dose is sufficient to restore a normal rhythm^{40,41}. If, however, the arrhythmia continues and no untoward effects from the test dose develop in six to twelve hours, the administration of the drug is resumed in doses of 0.3 to 0.4 gram at four to six hour intervals until normal rhythm is restored or until the appearance of toxic symptoms necessitates the discontinuance of the drug. After the restoration of the normal rhythm, a daily maintenance dose of 0.2 to 0.4 gram or more may be required to prevent recurrence of the arrhythmia. Often the rhythm will remain regular even if the drug is stopped abruptly after the cessation of fibrillation. In this type of case quinidine is almost invariably successful in restoring normal rhythm, and the patient often remains well indefinitely without further treatment.

The total amount of quinidine required to restore normal rhythm varies greatly. As already noted, a single dose of 0.2 gram may be sufficient

In some instances, however, very large doses up to three or four grams per day may be required (Lewis¹) Kohn and Levine⁴⁰ found no constant ratio between the duration of the arrhythmia, the clinical condition of the patient, and the amount of quinidine necessary to produce a normal rhythm. They found 0.2 gram of quinidine sufficient in one patient with moderate cardiac enlargement and congestive failure, in whom fibrillation was known to have existed for two and one-half months. In another patient, whose arrhythmia was of but a few days' duration, 10.5 grams of the drug were necessary before the rhythm became regular.

In thyrotoxicosis, auricular fibrillation may require no special treatment, since the adequate management of the primary cause often will result in a spontaneous cessation of the arrhythmia. If, in the absence of organic heart disease, such desired results fail to develop within one to three weeks after thyroidectomy, quinidine therapy will usually restore normal rhythm. A resumption of fibrillation after such restoration of regular rhythm usually signifies either that an insufficient amount of the gland was removed, or that some other additional cause was responsible for the arrhythmia.

In hyperthyroidism with normal rhythm, the important indication is the control of the thyrotoxicosis. The early use of iodine, glucose and surgery will tend to prevent the appearance of auricular fibrillation. It is questionable whether quinidine should be used prophylactically in such instances. Statistics bearing on this point are not now available.

The paroxysmal type of auricular fibrillation often requires no special treatment. As already noted, in about 80 per cent of the cases the paroxysms cease spontaneously in less than two days, in many the attacks last but a few minutes to a few hours, and only in very rare instances does a typical attack continue longer than one week (Parkinson and Campbell²¹). In paroxysms of relatively long duration treatment is indicated in accordance with the general principles already outlined. Quinidine in doses of 0.1 to 0.4 gram twice or three times daily may also be used prophylactically in cases subject to frequently recurring attacks.

Auricular fibrillation associated with a slow apical rate not the result of treatment is quite rare and usually signifies the presence of organic heart block. In such cases no special therapy is required apart from the measures indicated by the underlying cardiac condition. However, in the very rare instances where the auricular fibrillation and slow rate are associated with an otherwise normal heart, an attempt should be made to abolish the arrhythmia with quinidine.

Congestive failure is usually significant of grave organic heart disease. However, as has been pointed out above, severe congestive failure may result from untreated auricular fibrillation apart from any other disease of the heart. In such a case quinidine preceded by digitalization may bring about complete and lasting recovery.⁴¹

UNTOWARD EFFECTS OF QUINIDINE

Kohn and Levine⁴⁰ list the following as the most frequent symptoms of quinidine intoxication "Nausea, vomiting, epigastric distress, diarrhea, headache, palpitation, tinnitus, fear, mental depression, flushing, sweating, syncope, and a feeling of apprehension" They quote Carr and Spoene-man⁴⁸ who consider a rise in the pulse rate to 130 as an indication for the withdrawal of quinidine, since such a rise in the rate points to vagal paresis. Skin manifestations such as scarlatiniform rashes and urticaria may occur. The occurrence of embolic phenomena has already been referred to. Sudden death other than of embolic origin is also occasionally observed, possibly due to respiratory paralysis⁴⁰ or to ventricular fibrillation.

TREATMENT OF QUINIDINE INTOXICATION

The milder symptoms of quinidine overdosage are relieved by the discontinuance of the medication, as the drug is rapidly eliminated by oxidation and excretion.⁴⁷ In cases of severe intoxication with symptoms of respiratory embarrassment, life may sometimes be saved by artificial respiration and the intravenous or intracardiac administration of large doses (15 grains) of caffeine sodiobenzoate.⁴⁰

COMPARATIVE EFFECTS OF QUINIDINE AND DIGITALIS UPON FIBRILLATION

In properly selected patients quinidine is effective in restoring normal rhythm or in preventing paroxysms in from 70 to 80 per cent of the cases. It is slightly more effective in younger patients (Organ, Wolff and White³³). This may be due to the fact that in the older age group, cardiovascular changes are more apt to exist without their being clinically detectable.

Digitalis is useful in slowing the pulse rate and may possibly diminish the frequency of transient attacks (Parkinson and Bedford⁴⁹). However, in established fibrillation, digitalis alone is not effective in restoring normal rhythm (Friedlander and Levine¹⁸).

"SURGICAL SHOCK" FACTORS IN PNEUMONIA

By EDMUND ANDREWS, M D , and HENRY N HARKINS, M D , Ph D ,
Chicago, Illinois

UNDERHILL and his associates^{1, 2, 3} did experiments at the time of the World War on the effects of the gases chlorine, phosgene and chlorpicrin. He showed that these lung irritants caused massive pulmonary edema with marked blood concentration. The total extent of this edema was not measured, but it was shown to be a protein-containing exudate. The average increase in blood concentration of four dogs which inhaled 41 to 50 parts per million of phosgene for one-half hour was 166 per cent of the control value as measured by hemoglobin readings. Underhill⁴ showed that in the influenzal pneumonia that occurred during the War, a similar pulmonary edema with resultant blood concentration was one of the chief lethal factors. He showed that fluid introduction might be of aid in this condition and that by following blood concentration changes, prognostication was greatly aided. In 11 cases with no complications, nine had a hemoglobin percentage of over 120 with values going up to 140. Moon^{5, 6} also noted red counts of 6,000,000 to 8,000,000 with correspondingly high hemoglobin percentages in influenzal pneumonia. He noted at autopsy that there was extreme capillary congestion of the pulmonary and gastrointestinal mucosa, that the lungs were wet and bloody and that frequently there was an effusion of reddish fluid into the serous cavities. Moon and Morgan⁷ produced pulmonary edema in dogs by injections of sodium glycocholate with increase in the red count and hemoglobin percentage (2,300,000 and 35 per cent increase respectively in one dog). All of these reports indicate that pulmonary edema may result from both exogenous and endogenous toxic factors.

Underhill³ analyzed the edematous lungs of animals resulting from inhalation of war gases and found that the water content per unit weight of tissue increased. Sunderman⁸ reported that in pneumonia the serum albumin decreased, the globulin increased and the total protein tended to remain within the normal or lower normal limits. Moon and Crawford⁹ reported a case of shock syndrome in mercuric chloride poisoning with death 37 hours after taking the poison. In this patient there were 1500 c c of blood tinged fluid in the peritoneal and pleural cavities. The lungs weighed 1800 gm after considerable fluid escaped from them. This means that in the lungs and three major cavities there was an exudation of about 3000 c c, which if essentially blood and plasma is of great significance.

STUDY OF CASES

Necropsy records of a series of patients dying with pneumonia at the University of Chicago Clinics were studied. Twenty-three such cases were

From the Department of Surgery, University of Chicago

used for the present report and the weight of the lungs and presence of pleural fluid noted. These cases represented deaths from lobar, broncho- and terminal pneumonia and in many instances the pneumonia was not the sole cause of death. In these cases the average excess lung weight (assuming normal lungs to weigh 600 gm) represented 2.45 per cent body weight. In several instances there was appreciable pleural fluid. This brought the total increase to 2.81 per cent body weight as shown in table 1. No chemical analyses were performed, but if this amount represents blood or blood plasma it is of considerable significance.

TABLE I

Increase in Lung Weight and Exudation of Pleural Fluid in Patients Dying with Pneumonia

* The excess of the lung weight over the arbitrary normal of 600 gm is tabulated in this column.

† Blood pressure 142 systolic six days before death.

‡ Blood pressure 130/70 eleven hours antemortem.

EXPERIMENTS

Since no lungs from human pneumonia patients were available for chemical analysis at the time this study was carried out, the lungs of two distemper and one pneumonia dog were analyzed and compared with those of a normal dog. Analyses of the entire lungs were performed and the

nitrogen and protein contents determined on selected portions of the liquid solution of digested lung as shown in table 2, rather than on small bits of solid lung. These analyses show that the nitrogen and protein content in the abnormal lungs is essentially the same as in the normal lungs, indicating that the pneumonic exudate was protein containing. For the sake of more conclusive results the lack of great increase in total weight of these lungs as compared to normal lungs is not helpful. However, in certain instances different portions of the lung (right or left side) were markedly edematous without corresponding dilution of the protein content.

TABLE II

Nitrogen and Protein Content of Normal and Inflammatory Lungs in Experimental Animals *

Dog No	Condition	Body Wgt Kg	Lung Wgt Gm	Lung Wgt as Per Cent Body Wgt	Lung	Lung Wgt Gm	Per Cent Nitrogen	Per Cent Protein
1	Normal control	6.8	132	1.9	Left	51	2.20	13.68

COMMENT

The amount of fluid lost in the various pneumonia cases is extensive, averaging 2.81 per cent body weight. The special significance of loss of this amount of fluid depends on the interval of time during which the loss occurs and on the composition of the fluid. As seen from table 1, death usually occurred several days after the onset of the disease. Since it is difficult to tell whether most of the fluid was lost over the entire course of the disease, or as a terminal phenomenon, the time factor is uncertain. Naturally the loss of considerable blood or fluid in a few hours is of much more serious

important than the loss of a similar amount of fluid over a period of several days. Likewise the composition of the fluid was not determined in any of our cases and only from analogous animal experiments was its plasma-like nature inferred. Furthermore, the presence of shock was not demonstrated in any of the 23 patients as few blood pressure readings were taken. Only two patients had blood pressure readings after entrance and none closer than 11 hours to the time of death.

This quantity of fluid when lost from the circulating blood stream can, however, be of lethal significance. Studies of the amount of plasma-like fluid lost in various other shock-like conditions, both clinical and experimental, indicate a loss of the following amounts: burns 3.2 per cent body weight (Blalock¹⁰), 2.2 per cent (Harkins¹¹), freezing 2.6 per cent (Harkins et al¹²), release of an extremity constrictor 3.5 per cent (Wilson and Roome¹³), bile peritonitis 2.5 per cent (Harkins et al¹⁴), intestinal manipulation 4.5 per cent (Blalock¹⁵), and plasmapheresis 2.6 per cent (Johnson and Blalock¹⁶), 4.0 per cent (Harkins and Harmon¹⁷). No attempt will be made at this time to demonstrate that the loss of this amount of plasma-like fluid was the cause of death in these particular conditions, but the comparison between these figures and the average loss of 2.81 per cent fluid into the lungs and pleural cavities of our patients is pertinent. While this average is at the borderline of the range of fluid loss serious in these other conditions, in several individual pneumonia patients the figure was much higher. To our knowledge little attention has been paid to the possible importance of this fluid loss in pneumonia.

CONCLUSIONS

In a series of 23 pneumonia patients there was a combined increase in weight of the lungs and exudation of pleural fluid amounting to 2.81 per cent body weight. Under certain conditions the loss of this much fluid from the circulating blood stream may be significant and a condition resembling surgical shock may possibly result.

ENCEPHALITIS DUE TO UNDULANT FEVER, REPORT OF FOUR CASES¹

By E PERRY McCULLAGH, M D, *Cleveland, Ohio*, and H M CLODFELTER,
M D, *Columbus, Ohio*

It is a little more than 10 years since undulant fever was recognized in parts of the world remote from the Mediterranean basin. Since then cases have been reported from many parts of Europe, Asia, and this continent. In 1933, 1,787 cases were reported in the United States and it seems highly probable that this was but a small proportion of the true total incidence. Among the complications of the disease the occurrence of meningitis has been described. Hartley, Millice, and Jordan,¹ in 1934, reported a case of meningitis due to undulant fever in which the patient recovered. In their case, there was a prodromal period of four weeks which they suggested could have been due to encephalitis. Krabbe² reported a case of meningomyelitis due to Bang's disease but made no mention of a true encephalitis.

We wish to present four cases of encephalitis in one of which features highly suggestive of hypothalamic and pituitary damage were present. In all the cases, the agglutination test or skin test indicated that undulant fever was present and in all no other etiologic factor could be demonstrated. So far as we have been able to discover, this clinical manifestation of the disease has not been reported previously in the literature.[†]

CASE REPORTS

Case 1 The patient was a boy 14 years of age who had been well until four weeks before admission to the hospital. At that time he had an influenza-like infection and missed two weeks of school. When he returned to school, he felt much below par and did not take an active interest in school activities. The day before admission here, he complained that he could not see well and a severe headache developed.

Physical examination revealed a slight fever and marked choking of both optic discs with blindness in the right eye and very little vision in the left. The boy could not see well enough to permit study of the visual fields. Neurological examination and roentgenographic studies of the head revealed no other abnormalities. A lumbar puncture was done which showed an initial pressure of 190 mm of water with normal dynamics. Examination of the spinal fluid revealed findings which were not abnormal. The leukocyte count in the blood varied from 5,000 to 11,000 and the differential counts were normal.

Five days after admission, the patient complained of a generalized, severe headache and on that day he vomited. The fever continued to be present. Bilateral positive Babinski signs were present. An encephalogram revealed no abnormalities.

* Received for publication October 6, 1936.

From the Cleveland Clinic, Cleveland, Ohio.

[†] Since these cases were collected, we have been interested in three cases of undulant fever associated with papilledema reported by Rutherford³. He does not emphasize the presence of encephalitis as much as we have done, but we feel that all these cases fall into the same group.

The diagnosis at this time was encephalitis, but since the appearance of the optic discs indicated increased intracranial pressure, a right subtemporal decompression was done in an effort to restore the patient's vision. The decompression did not bulge postoperatively. The fever persisted, varying daily between 97.7° and 103° F and occasionally rose as high as 104° F. An agglutination test for undulant fever was done and was found to be positive in a dilution of 1:640.

Numbness of the legs and retention of urine developed, and in view of the previous findings the diagnosis was changed to encephalomyelitis. The vision began to return, the neurological signs began to diminish, and the patient was discharged on the twenty-ninth postoperative day. The temperature was 101° F.

Thirty days after his discharge from the hospital, the patient's temperature was normal but he was still weak. Two months later his vision had returned and he was free from symptoms and signs insofar as his original illness was concerned.

This boy, who lived on a farm, had consumed much raw milk, his father was found to have a positive undulant fever agglutination test.

Case 2 A woman 55 years of age was admitted to the Clinic in April 1934, complaining of "headaches and vomiting." Seven months before admission, fever and chills had been present for four weeks and no cause was found. Two months before admission, similar symptoms had been present for 10 days and at this time, headaches and vomiting began which did not stop. She was in a hospital elsewhere for one week and was in a stupor during that time. A lumbar puncture had showed no abnormalities.

The patient entered the hospital for observation. Roentgenographic studies of the head, chest, kidneys, ureters, and bladder revealed no abnormalities. No evidence of tuberculosis could be found by roentgen examination or culture from voided and bladder urine. There was a slight haziness of the optic discs but the visual fields showed no changes. Lumbar puncture revealed no abnormal findings. The initial spinal fluid pressure was 170 mm, and following removal of 6 cc of spinal fluid was 110 mm of water. The total protein was 20 mg and no globulin or cells were present. There was a suggestive bilateral digital reflex. It was noted that a slight fever was present while the patient was in the hospital. A diagnosis of mild encephalitis was made and she was allowed to go home.

The patient was readmitted for study and recheck 10 months later. The headaches were still present but less severe. The vomiting had ceased but there was some nausea, and the temperature rose to 100° F each day. Undulant fever agglutination tests were negative but an intradermal test using 0.1 cc of Brucellin was markedly positive, and with this test the temperature rose to 100.5° F. Culture from a duodenal drainage revealed diphtheroid bacilli and yeast but no organisms of undulant fever. The positive reaction of the intradermal test in our opinion established the diagnosis of chronic undulant fever as the only demonstrable cause of this patient's symptoms.

Case 3 The patient was a young married woman 25 years of age who entered the Clinic May 24, 1934, complaining of fatigue, gain in weight, and scanty menstruation which had been present for two years. The onset of her symptoms occurred one and one-half years before this examination with an acute illness which was characterized by fever and extreme exhaustion, and the patient had never been well since that time. Somnolence became a very bothersome symptom, she had difficulty in awakening before noon each day and her previously excellent memory had become poor. Exhaustion had been so severe that bed rest was necessary for one or two weeks at a time. No headaches, diplopia, polydipsia, or polyuria were present. Libido began to decrease slowly until sexual desire was completely gone. About 25 pounds in weight had been gained. Menstrual periods had begun at the age of nine but had been irregular until the age of 14 when they became regular.

A fairly normal pregnancy terminated eight months before our examination Six weeks after delivery, the periods began again but they had become more scanty each month until at the time of our examination, very scanty menstrual flow occurred for part of one day each month

Physical examination revealed a woman 61 5 inches tall who weighed 145 pounds The temperature and pulse rate were normal and the blood pressure was 98 mm systolic and 70 mm of mercury diastolic The distribution of body fat was of the cerebral type The optic discs were hazy but examination of the visual fields revealed them to be within normal limits No clinical signs of hypothyroidism were present Laboratory study revealed the urine to be normal as was the blood except for 45 per cent lymphocytosis Complete blood chemistry examination revealed no abnormalities except in the level of the cholesterol which was 231 mg per 100 c c A glucose tolerance test was done using 100 grams of glucose orally Blood sugar determinations fasting one-half, one, two, and three hours following glucose administrations were 88, 117, 105, 84, and 78 mg per 100 c c The basal metabolic rates averaged minus 12 per cent Roentgenograms of the head revealed no evidence of pathological change and dental roentgenograms revealed no evidence of infection

Bio-assays revealed a positive Friedman test which was probably due to antuitrin-S (pregnancy urine prolan) which had been administered until four days before admission Assay for urinary estrin by the Kurzrok method on a 24 hour specimen of urine showed 3 4 and 4 0 rat units on two examinations

Hypothalamic damage was indicated because of the rather marked weight gain which took place in the presence of fever, the fact that it was distributed as in pituitary or cerebral disease and because of the excessive somnolence which occurred Damage to the pituitary region was strongly suggested by the marked diminution in libido and by the occurrence of hypomenorrhea The metabolic rate and glucose tolerance were not decidedly abnormal but were consistent with some damage to these structures

A diagnosis of pituitary hypothalamic syndrome following encephalitis was made which corroborated the diagnoses not then known to have previously been made separately by Dr W James Gardner and Dr Louis J Karnosh

After 10 months, no improvement was found and Dr Frank J Geib suggested that the condition might be due to undulant fever The agglutination test was positive in a dilution of 1 60 and severe reactions occurred after the administration of undulant fever vaccine in amounts less than 0 5 c c Further investigation of the temperature showed that fever recurred at regular intervals For from 16 to 17 days, the patient would be free from fever, then for eight days fever would be present, only to disappear for about 16 days again The symptoms were all aggravated during the period of fever

With our knowledge of the preceding cases, we felt that it was logical to presume that undulant fever caused this patient's symptoms Undulant fever vaccine was administered and one year later the patient was somewhat improved, but some reaction still occurred after the use of the vaccine and fever recurred at regular intervals During the periods when the patient was free from fever, there was little local or general reaction to vaccine, but both local and general reactions increased during the febrile period

Case 4 The patient was an unmarried woman 31 years of age who complained of diplopia, headache, and staggering gait She had been well until eight years before this examination when menstrual irregularity developed which was associated with considerable excitability That year a partial oophorectomy was performed with no immediate change in the menstrual cycle Later, the periods slowly became more frequent and more prolonged It was not long after the operation until the patient had a "nervous breakdown" which lasted most of the year Fairly frequent attacks

of fever occurred and during these attacks she was confined to bed. Her symptoms then disappeared except for the menstrual irregularity.

Seven years after the onset of the first symptoms, the patient began to be extremely excitable again, and this was accompanied by persistent diplopia. The nervousness became so severe that she was confined to a sanatorium for five weeks but showed no improvement. Later, drowsiness progressed to coma and she was confined to the hospital for three weeks. The temperature varied from 105° to 107° F, and the neurologist in charge made a diagnosis of encephalitis. The patient was discharged from the hospital. At the time of discharge she weighed about 60 pounds. The coma and somnolence subsequently disappeared and her weight increased to 125 pounds.

One year later, in the summer of 1935, the patient again began to have severe headaches with marked persistent diplopia. The gait was staggering and there was distinct static ataxia. The diplopia was relieved with prisms but monthly examination of the visual fields showed a marked and progressive concentric diminution of the entire field. Undulant fever agglutination tests had given negative findings.

The patient reentered the hospital in December 1935. General physical examination revealed no abnormalities except those mentioned above. The basal metabolic rate was minus 11 per cent, the blood Wassermann was negative, the urine was free from sugar, albumin, pus, and casts with a daily output of approximately 2,000 c.c. The hemoglobin was 12.5 grams per 100 c.c. of blood, the red blood cells numbered 5,200,000, the leukocytes numbered 7,500 with 40 per cent lymphocytes. The daily temperature was about 99.4° F. Roentgen examination of skull and chest showed no abnormal changes. Lumbar puncture showed a spinal fluid pressure of 80 mm. of water with normal dynamics. The cell count was 4 with a negative Wassermann reaction.

An undulant fever skin test with 0.05 c.c. of undulant fever vaccine (Jensen-Salsbery) was markedly positive, producing an abscess after 72 hours. This sloughed, then healed after 10 days. Vaccine therapy was instituted with marked local and systemic reactions.

Diagnosis Chronic undulant fever encephalitis

DISCUSSION

The relationship between encephalitis and undulant fever first was suspected in the first case and this was proved insofar as was practicable. In the second case, the diagnosis of encephalitis was made 10 months before undulant fever was suspected as the etiological factor. In the third case, decreased menstrual flow was associated with somnolence and other evidence of hypothalamic damage.

Since we have depended to a rather large extent on a markedly positive intradermal test for the diagnosis in two of our cases and since this method has not been as widely used as the agglutination test, we wish to explain why we consider that such a diagnosis is warranted.

Cutaneous hypersensitiveness to *Brucella abortus* has generally been considered by those who have investigated it as a good criterion in the diagnosis of undulant fever. However, it need not necessarily be considered as evidence of active infection. From the work which has a direct bearing on this point, the following reports in the literature may be cited. In 1918, Fleischer and Meyer⁴ showed that infection of guinea pigs with *Bacillus abortus bovinus* always produces cutaneous hypersensitiveness. In 1929, Giordano⁵

reported that the intradermal injection of a suspension of killed *Brucella abortus* yielded unmistakably positive reactions in 25 known cases of undulant fever and gave negative results in 99 of 100 controls. Levine⁶ in 1931 reported the results of intradermal tests in 365 individuals. Using suspensions of *Brucella abortus* antigens, cutaneous hypersensitiveness was shown in 27 cases and in only four of these was there no history of undiagnosed illness.

Yeckel and Chapman⁷ in 1933 reported the results of 250 intradermal tests in which killed bacterial suspensions of *Brucella abortus* were used. Fourteen definitely positive reactions were obtained and in only one instance was there no history of possible undulant fever. These workers concluded that, in the presence of a negative agglutination reaction, the intradermal reaction may be positive and thus lead to a definite diagnosis. Goldstein⁸ found 26 positive cutaneous reactions to saline suspensions of *Brucella abortus* among 253 unselected cases in an area where undulant fever was prevalent, and 13 of these patients gave histories indicating possible sources of infection with *Brucella abortus*. Favorite and Curtis⁹ found positive skin tests in 10 known cases and only one positive reaction was obtained in testing 90 controls. A subsequent history in this one case was very suggestive and the patient was shown to have an agglutination titer of 1:250.

In our own series of 90 unselected cases in which a tentative clinical diagnosis of undulant fever had been made, the skin test was performed 55 times. In 29, the intradermal reaction was definitely positive despite negative agglutination tests.

We have seen two cases in which the skin test was negative, yet positive undulant fever agglutination was found in testing the sera. In neither was there a definite clinical diagnosis and there were other extenuating circumstances. In the first case, the agglutination titer was only 1:10 and autopsy showed the presence of miliary tuberculosis. In the second case, the agglutination test was positive in one laboratory but negative in another. Blood cultures and opsonic activity¹⁰ have not been determined in our cases.

In the intracutaneous tests reported here, with the exception of Case 2, 0.05 to 0.1 c.c. of Jensen-Salsbery undulant fever vaccine has been used. This contains a heat-killed suspension in normal saline of *Brucella melitensis*, variety *abortus* and *suis*, 50 per cent of each preserved with 0.5 per cent phenol. Each cubic centimeter contains six billion killed organisms. In Case 2 Brucellin was used. The Brucellin used in this test was made in Huddleston's laboratories where it was developed by Hershey. It is a soluble nucleo-protein fraction of the three species of *Brucella* in 1:1000 dilution in slightly alkaline physiological salt solution.

The area of redness resulting from such an injection may be from three to seven centimeters in diameter and occasionally larger. It is edematous, hot, and tender and at times lymphangitis, adenitis and fever may be present. In some cases, a necrotic core or abscess forms and, in many patients, healing takes place slowly, leaving an area of pigmentation which remains for

many weeks. Those intradermal reactions which disappear within two days may be considered to be of little significance.

In evaluating the significance of such a reaction, the history of the patient must be considered. In addition, it is frequently of significance that small doses of vaccine, which are given for therapeutic purposes, produce unusually great responses in temperature. Where other causes for fever and accompanying symptoms can be eliminated and, in the presence of a strongly positive intracutaneous reaction, we believe a diagnosis of undulant fever is warranted.

Two patients (Cases 1 and 2) have shown improvement without specific treatment. The third patient failed to improve without specific treatment but has shown some improvement since it has been instituted. While there is improvement at present in the condition of the fourth patient, her prognosis seems uncertain in view of the history. While the authors realize that the evidence presented above does not constitute proof that encephalitis in these cases was actually caused by growing undulant fever bacilli in the perivascular spaces or nervous tissue of the brain and cord, the findings are nevertheless highly suggestive that such was the case.

SUMMARY

- 1 Four cases of encephalitis have been presented.
- 2 The etiological factors have apparently been the organisms of undulant fever as determined by agglutination tests in two cases and by intracutaneous tests in the other cases.
- 3 In one of the cases, evidence suggestive of hypothalamic or pituitary damage was present.

NONVALVULAR HEART DISEASE UNDER THE AGE OF FORTY-SIX YEARS ¹

By SMITH O DEXTER, JR., and DANA L FARNSWORTH,
Boston, Massachusetts

INTRODUCTION

NONVALVULAR heart disease, often misnamed "myocarditis," is generally regarded as a condition of degenerative nature in older patients, attributable to coronary sclerosis or hypertension or both. That it may be frequently found in youth is not well known, nor are the etiological factors behind it generally appreciated.

Because of the interest and obscurity of youthful nonvalvular heart disease, we have undertaken to review a large number of cases in the pathological records of the Massachusetts General and Boston City Hospitals, focusing our attention upon the myocardial lesions which were reported. We have limited the study to younger patients and so have arbitrarily excluded those cases over 45 years of age, in order to reduce the preponderance of coronary sclerosis and hypertensive heart disease that might mask other conditions. The more recent years were chosen because the necropsy records were more complete. The cases reviewed all came to autopsy between the years 1920 and 1933. In selecting the cases we have included all those with hearts showing no valvular deformities or congenital defects, but with muscle injury recent or healed, or increase in heart weight to 350 grams or more in women and to 375 or more in men. For children we accepted the figures given by Viëtor² and Muller³ as the normal range:

Birth	20 to 25 grams	2 years	45 to 55 grams
1 month	15 to 20 grams	4 years	65 to 75 grams
6 months	20 to 25 grams	8 years	95 to 105 grams
1 year	30 to 40 grams	12 to 16 years	150 to 250 grams

In the course of this study we have reviewed 4,531 cases in the records of the Massachusetts General (2,600) and Boston City Hospitals (1931). From this group 250 cases were selected which fulfilled the requirements stated above. The pathologic reports were studied with special reference to cardiac findings, although in many instances the description was limited to a routine gross examination. The work was supplemented by a survey of the clinical records of the cases selected from the pathological reports, with particular emphasis on such points as duration of the disease, degree of hypertension, anemia, and clinical and laboratory data. The material has been combined in the appended charts and will be discussed in detail under appropriate sections.

¹ Received for publication January 27, 1937.

From the Medical and Pathological Departments of the Massachusetts General Hospital and the Boston City Hospital.

Undoubtedly the most accurate way of estimating the weight of the normal heart is through the use of Smith's² coefficients 0.43 per cent of body weight for men and 0.40 per cent for women. However, since the weight of the patients was not regularly included in the clinical records, the method was not applicable in this instance. The limits of heart weight up to 350 grams for women and 375 grams for men, chosen at the advice of Dr. Tracy Mallory of the Pathological Department of the Massachusetts General Hospital, were placed somewhat higher than most estimates to compensate for the small amount of aorta (at the most 20 grams) which is included in weighing the heart.

In spite of the most careful examination of clinical records, it is impossible to exclude a past hypertension of which there is neither history nor evidence at the time of examination. In several of the cases selected the size of the heart seemed out of all proportion to any initiating cause that we could find. When the blood pressure readings consisted only of a single determination with the patient in congestive failure, it can hardly be said that hypertension had been excluded as a cause. However, the number of cases in which this probability existed was not very large, though the source of error must be taken into account in evaluating the results.

DETAILS OF THE PRESENT STUDY

Of the 4,531 necropsy records reviewed, 250 cases, or 5.5 per cent of the total number, were found to belong to the group which we have outlined. The pathological condition which was most commonly associated with myocardial abnormality was hypertension, frequently accompanied by nephritis, with acute and chronic infections a close second. The complete classification is given in table 1.

TABLE I

	Cases
1 Hypertension	97
(A) With nephritis	67
(a) Chronic nephritis	62
(b) Acute glomerulonephritis	5
(B) Without nephritis	14
(C) With other conditions	16
2 Acute and chronic infections	91
3 Blood disorders	27
4 Coronary occlusion	5
5 Congenital idiopathic hypertrophy	4
6 Hyperthyroidism	1
7 Cardiac failure of unknown etiology	8
8 Miscellaneous	17
Total	250

The highest incidence of these myocardial abnormalities was found in the group from 41 to 45 years of age, and the lowest from 11 to 15 years of age. Starting with a fairly high incidence in the first five years of life, there was a steady decline in incidence until the fifteenth year, following which there was a gradual rise. This variation is perhaps explained by the

progressive decline in acute infections of childhood up to the fifteenth year, and by the steady increase in other forms of heart disease after that time. Males predominated almost in the ratio of two to one (162 to 88). The age incidence for both males and females is given in table 2.

TABLE II

Age group (years)	Number of males	Number of females	Total
0 to 5	16	5	21
6 to 10	7	4	11
11 to 15	1	3	4
16 to 20	8	6	14
21 to 25	9	9	18
26 to 30	14	9	23
31 to 35	19	12	31
36 to 40	32	17	49
41 to 45	56	23	79
Total	162	88	250

HYPERTENSION

That hypertension is followed by cardiac hypertrophy in the great majority of cases has been frequently observed. Paullin, Bowcock, and Wood,⁹ in studying the complications of hypertension, found that cardiac hypertrophy occurred in 66.4 per cent of cases. In many cases of unexplained cardiac enlargement at the time of death, study of the records will show that a previous hypertension has existed. In 50 such cases O'Hare, Calhoun and Altnow¹² found that hypertension of varying grades had been present on earlier examinations, although during the terminal cardiac failure the pressure had dropped to normal.

The exact mechanism of cardiac hypertrophy is uncertain. That increased muscular work alone is insufficient to cause hypertrophy of the heart is shown by the fact that Marathon runners usually have hearts which are normal in size or even undersized.^{7, 8} Eyster's^{1, 4} demonstration of progressive cardiac hypertrophy in dogs after a temporary obstruction to blood flow in the aorta indicates that stretching of the muscle fibers may be the initial injury to which the fibers react by becoming hypertrophied. Whether this mechanism is operating in all cases of cardiac hypertrophy is uncertain, although it appears to be a rational explanation. The surprising absence of cardiac hypertrophy in some cases of prolonged hypertension may thus be explained by the supposition that the load was applied so gradually that dilatation never took place.

(A) *Hypertension with Nephritis*—The organic lesion elsewhere in the body with which abnormalities of the heart muscle were most often associated in the present series was chronic nephritis. Of the total of 250 cases, 67 or 26.8 per cent were found at autopsy to have one of the forms of

chronic nephritis* The factor which was common to the great majority of the cases in this group was hypertension Every case except one had a systolic blood pressure of 140 or more at the time of entry to the hospital, the one exception to this was a child of ten who had a blood pressure of 132/70, a distinct elevation for a child of that age A systolic pressure of 200 or over was observed in 32 of the 67 cases, and a diastolic pressure of 100 or over was found in 57 cases The heart weights in this group were all definitely above normal, the highest being 900 grams, and the average of the 65 adults (16 years and above) was 499.7 grams Those with a systolic pressure of 200 or over had hearts averaging 537.6 grams There is evidently some correlation between the degree of hypertension and the amount of hypertrophy, although other factors such as the duration of the hypertension, anemia, or intercurrent infections must also be considered

Aside from hypertrophy there were very few changes in the gross appearance of the hearts in these cases One showed small, flat yellowish areas in the epicardium and extending into the myocardium, while another had a few "milk patches" on the left ventricle and the right auricle The microscopic appearance of the heart muscle was no more characteristic than the gross appearance Thirty-one hearts were said to be normal microscopically, while 12 were not so examined In the remaining 24 cases the microscopic changes varied from diffuse fibrosis to perivascular areas of fibrosis with or without cellular infiltration In cases of malignant hypertension focal necroses were frequently described Edema of the stroma, fragmentation of fibers, and increase in size of individual fibers were also noted

Electrocardiograms were taken in but 22 of the cases and in 12 of these left axis deviation was noted This agrees with the work of Ziskin¹⁰ who found no constant changes in the electrocardiograms of 100 patients with hypertension, although 44 showed left axis deviation Additional electrocardiographic changes in our group were inversion of the T-waves, low or high origin of the T-waves, and slurring of the QRS waves

(B) *Hypertension without Nephritis* Fourteen cases of hypertension in which the renal factor was negligible have been grouped under the heading, "Hypertensive Heart Disease without Nephritis"

Nothing beyond minor degrees of arteriosclerosis was found in the kidneys of the "purely hypertensive" cases Since this form of heart disease is found largely in middle aged and elderly persons, it is not surprising that all our cases were in the upper range of our age group, between 38 and 45 years of age In about half of the cases cardiac failure was the cause of death, while in the others cerebral hemorrhage or pulmonary embolism were the terminal events The average weight of the hearts for this group was 545 grams Grossly most of the hearts were hypertrophied and dilated, while microscopically generalized and patchy fibrosis was noted The most

* Because of the necessity of condensing the article the tables of the individual cases have been omitted

common electrocardiographic changes were left axis deviation and inversion of the T-waves

(C) *Hypertension with Other Complications* This rather heterogeneous group of 16 cases has been separated from the other sub-groups because a definite hypertension existed as a complicating factor. In six of the cases acute infections, which, as will be shown later, are sometimes accompanied by cardiac enlargement, were present in addition to the high blood pressure. The myocardium in these cases was normal except for minor grades of hypertrophy. Four cases showed extensive cardiac infarction as well as an elevated blood pressure. In addition to recent or healed infarction, the hearts exhibited marked hypertrophy with an average weight of 662.5 grams. Since both cardiac infarction and hypertension are capable of producing enlargement of the heart, the part played by each is impossible to estimate. In the other six cases, in addition to moderate elevation of blood pressure, the following diagnoses were recorded: pyonephrosis with uremia, chronic tubo-ovarian abscess, exophthalmic goiter, carcinoma of a bronchus with small metastatic nodules, lymphoblastoma, and cirrhosis of the liver. Myocardial changes, except for slight increase in weight, were insignificant except for the tumor nodules in the case of carcinoma of the bronchus and fatty infiltration in the last two cases mentioned above.

2 ACUTE AND CHRONIC INFECTIONS

In 91 of the 250 selected cases acute and chronic infections were the primary causes of death. It is very difficult properly to evaluate the part played by the infectious process, since in many of the instances the marked cardiac enlargement indicated that another factor must have been at work. Those in which hypertension was known to have existed as a complicating factor have already been segregated into a separate group (1C). For purposes of discussion it is convenient to divide the cases in the following groups:

(A) *Acute Pulmonary Infections* In all acute infections there is probably some toxic action on the heart, but in pneumonia there is the added factor of stasis in the pulmonary circuit and anoxemia. In 1915 Newburgh and Porter,¹⁹ after injecting pneumonic blood into normal dogs, noticed that there was an initial loss of effectiveness of the heart as evidenced by a decreased stroke volume and lessened area of contraction. They observed, however, that this toxic effect wore off after a short while and that the heart rapidly readjusted itself to the altered conditions. So long as general nourishment was maintained and the initial dose was not too great the myocardium was quite able to cope with the toxin. In addition to this toxic effect, which in debilitated subjects may be quite marked, there is the added factor of increased resistance in the pulmonary circuit. Stone²⁰ found dilatation of the right heart in 39.4 per cent of 89 cases of lobar pneumonia and in 36.6 per cent of 112 cases of bronchopneumonia, while microscopi-

cally there was evidence of inflammatory and degenerative change in 61.9 per cent of 21 cases of lobar pneumonia and in 25 per cent of eight cases of bronchopneumonia. The whole heart was usually involved.

There were 32 cases of acute pleuro-pulmonary infections in our series, 23 of lobar pneumonia with and without complications, eight of bronchopneumonia with and without complicating conditions, and one of acute empyema. In all of these except one, the heart weight was above the average. The average weight of the hearts of the 28 adults was 413 grams.

In the majority of cases the myocardium was reported either as normal or as moderately hypertrophied or dilated. Microscopic examination was either essentially negative or not done in 23 of the cases, while in the others diffuse fibrosis was noted in four, cellular infiltration in two, fatty infiltration in one, and areas of necrosis and abscess formation in two. Four other cases of acute pulmonary infections were included under "Hypertension with Other Complications" because of a coincident high blood pressure.

(B) *Chronic Pulmonary Infections*. It has long been noted that chronic pulmonary disease, if obstruction to the pulmonary circulation is sufficiently great, results in a definite pulmonary hypertension with attendant strain on the right heart. Among the more common etiological agents are chronic bronchitis and emphysema, bronchiectasis, extensive fibrocaceous tuberculosis, thoracic deformities, extensive infiltrating tumors of the lungs, and endarteritis of the pulmonary vessels (Ayerza's disease). As Moschowitz²⁶ pointed out, obstruction to the pulmonary circulation by pressure upon or occlusion of the smaller vessels produces a hypertension which tends to engorge and dilate the right ventricle with eventual right sided hypertrophy. The added factor of pulmonary arteriosclerosis, which follows prolonged pulmonary hypertension, may serve eventually perhaps to aggravate the condition. When the right ventricle fails, the tricuspid ring is dilated and the effects are transmitted to the systemic venous circulation.

Long-continued bronchial asthma, especially when accompanied by emphysema, has sometimes been regarded as a cause of severe strain on the right heart, but recently Alexander and others,²⁴ in 50 such cases, were unable to find any evidence of myocardial damage as the result of asthma alone. Pulmonary abscess, unless extremely extensive, does not alter the mechanics of the lesser circulation, though it may exert a deleterious effect on the heart as a whole because of the toxemia. Tuberculosis, in addition to its pulmonary effects, may in rare instances involve the myocardium, producing lesions varying from disseminated miliary tubercles to large, caseous, tuberculous masses. Obliterating endarteritis of the pulmonary vessels (sometimes unsatisfactorily called Ayerza's disease) is a very rare condition which usually does not have a luetic origin. The pathological picture is that of an occluding endarteritis of the smaller pulmonary vessels with dilatation of the pulmonary artery and hypertrophy of the right heart. Cheney²⁵ considers it to be a distinct disease entity, while Moschowitz²⁶

regards it, in the absence of proved etiology, as merely a syndrome which may be secondary to hypertension and sclerosis of the pulmonary circuit

There were 17 cases of chronic pulmonary disease in our series in which definite cardiac changes were observed. Pulmonary abscess, bronchopneumonia, bronchiectasis, and pulmonary tuberculosis were the most frequent disorders, though there were two cases of emphysema, one case of silicosis and emphysema, and two cases of endarteritis obliterans.

Generalized enlargement of the heart was noted in five cases, left ventricular hypertrophy in one, and right ventricular hypertrophy in four, although in this last group the total heart weight was within normal limits in two. Microscopic changes were not particularly important or characteristic.

In one case of miliary tuberculosis a few miliary tubercles were found in a heart which was otherwise normal, while in another case of tuberculosis the incidental finding of a small rhabdomyoma was the only cardiac abnormality. The other changes reported were enlarged fibers in a case of right-sided hypertrophy, associated with bronchiectasis and emphysema, fatty infiltration in a case of tuberculosis and chronic alcoholism, small areas of scarring in a case in which a positive Kahn reaction and aortic changes brought up the question of cardiovascular syphilis, and an eosinophilia in a case of obliterating endarteritis. Electrocardiograms showed left axis deviation in the case of left ventricular hypertrophy and in one case of generalized enlargement and right axis deviation in a case of right ventricular hypertrophy. In three cases, other than the one noted above, the Kahn reaction was positive, although there was no evidence of cardiovascular syphilis.

(C) *Acute Infections Other than Pulmonary* Acute infectious diseases in general cause no permanent injury to the heart muscle, though temporary functional derangement has been frequently observed. When there has been a concurrent intense toxemia, examination may show myocardial changes of a non-specific nature. Warthin¹² and others have described necrosis and hyaline degeneration of muscle fibers with the appearance of fatty changes and cloudy swelling in diphtheria, while Hamman³² found fragmentation and swelling of the muscle fibers, interstitial edema, and perivascular fibrosis in severe typhoid fever. In other acute infections similar pictures have been reported, when death has occurred while toxemia has been intense. However, the lack of permanent injury is indicated by the return of normal function after the infection has subsided. White and Jones³¹ were unable to find clinical evidence of cardiac damage in 100 cases five to eight years after severe diphtheria, while Brow,²⁸ in spite of Thayer's (quoted by Brow) assertion that elevated blood pressure and vascular sclerosis were frequent sequels of typhoid fever, found no indication of permanent ill effects in 65 cases of this disease one to 13 months after recovery. Rheumatic fever occupies a somewhat unique position among

acute infections, at least so far as cardiac involvement is concerned. Although endocardial damage is responsible for most of the late crippling effects, yet during the acute infection a pancarditis is almost the rule. After the acute disease is well established, the typical myocardial lesions are the Aschoff bodies, perivascular inflammatory reactions with round cell and giant cell infiltration. These lesions usually clear up after the acute infection has passed, although residual sclerosis has been reported.

That functional cardiac impairment does take place during the height of acute infectious disease is amply shown by electrocardiographic studies. Brow,²⁸ Burnett and Piltz,¹⁷ and others have reported electrocardiographic changes in diphtheria, rheumatic fever, typhoid fever, pneumonia, influenza, and other acute infectious diseases. Prolongation of the P-R interval, slurring of the QRS complexes, and inversion of the T-waves are the usual findings and indicate disturbance of the conduction mechanism and myocardium. In diphtheria, particularly, conduction changes varying from simple prolongation of the P-R interval to complete A-V block as well as alterations in the T-waves are frequently noted. Except in rare instances it is the rule for these signs to disappear in a few months. There were 35 cases in our series showing myocardial damage or hypertrophy in acute infectious diseases.

In the five cases of diphtheria, the gross changes were not remarkable except for slight to moderate enlargement in three. Microscopically four of them showed hyaline degeneration with necrosis of fibers and cellular infiltration. The two cases of typhoid fever had essentially normal hearts except for moderate increase in weight. Three cases of scarlet fever were included because of the focal necroses and cellular infiltration of the myocardium. In one of them the lesions suggested Aschoff bodies. In two of them, one associated with acute nephritis and the other with pyelonephritis, there was definite cardiac enlargement when the age of the patient was taken into consideration. Of eight cases of meningitis due to the meningococcus or the streptococcus, the heart weight was above the normal in seven. Microscopic examination showed focal necroses in three of these. A case of encephalitis and bronchopneumonia showed occasional necrotic fibers and slight increase in heart weight. In the remaining 16 cases pyogenic infections were the immediate causes of death. The diagnoses included septicemia, pyemia, purulent arthritis, osteomyelitis, localized abscesses, and peritonitis. Definite increase in weight was noted in 11 and slight increase in three. In six cases microscopic examination showed no abnormalities and in two it was not done. In the remaining eight cases changes varied from focal fibrosis to necrosis and actual abscess formation. Abscess formation in the heart was found in cases of pyemia and formed a part of the general process.

Electrocardiograms were taken in four of the diphtheria cases. In three of them there was definite evidence of disturbance in the conduction

mechanism, while the fourth was normal. A tracing was made in one of the pyemic cases and was not remarkable except for left axis deviation.

No case of acute rheumatic infection is included in this series because in each case there was some associated valvular disease. Rare cases do exist of myocardial rheumatic involvement with little or no valvular disease, but none were found in the groups from which our series was drawn.

(D) *Chronic Infections Other than Pulmonary* The effect of focal infections upon the heart is not very definitely understood. Bacterial endocarditis is infrequently associated with them, but no definite myocardial lesions have been found which may be related to focal infections. Aggravation of an existing heart disease or rarely minor arrhythmias may occur, but the relationship is far from certain.

There were seven cases of chronic non-pulmonary infectious disease with abnormalities of the heart without valvular deformities in our series. In five of them, the heart weight was definitely increased, in one the weight was borderline, and in one it was within normal limits. In three of the cases chronic infection of the kidneys undoubtedly produced some renal insufficiency, especially since in two cases only one kidney was functioning. In one case of luetic myelitis, the healed luetic aortitis and microscopic arterial changes may have accounted to some degree for the moderate increase in heart weight. Other microscopic changes were not remarkable except for the questionable Aschoff bodies in a case of a long-continued pyemic process with multiple septic joints.

3 DISEASES OF THE BLOOD

Enlargement of the heart in severe anemias has been noted clinically by several observers and has been confirmed at necropsy. Gautier³⁷ reported demonstrable enlargement in 20 of 22 patients with severe chlorosis, while other writers have published series of cases of pernicious anemia in which this phenomenon was noted in from 30 per cent to 95 per cent. Goldstein and Boas³⁴ found extension of the heart borders by percussion in 23 of 39 cases of pernicious anemia, six of them verified by roentgen-ray. Twelve of this group which came to autopsy showed marked cardiac dilatation with gross weights varying from 250 to 460 grams, averaging 330 grams. "Tigering" of the myocardium was observed in six cases. That these changes are not peculiar to pernicious anemia but accompany any severe anemia is demonstrated by the observations of Goldstein and Boas,³⁴ Ball,³⁸ and others. Ball cited a case in which electrocardiographic changes characteristic of left ventricular preponderance practically disappeared with restoration of the normal blood level.

Anoxemia has been suggested as the cause of the dilatation and is probably the principal factor at work. There is undoubtedly some degree of hypertrophy in long-standing anemias, which may result from the cardiac dilatation. Fahr and Ronzone³⁵ reported an increase of as much as 250

per cent in the minute volume of the heart output, in one case of severe pernicious anemia. This compensatory mechanism is made possible by accelerated beat, increased stroke volume, and decreased viscosity of the blood.

In leukemias there is, in addition to the marked accompanying anemia, the weight of the infiltrating cells, which may in some cases be sufficient to produce an appreciable increase in heart weight.
